Introduction

Welcome to the *Official Red Hat Linux Reference Guide*.

The *Official Red Hat Linux Reference Guide* contains useful information about your Red Hat Linux system. From fundamental concepts, such as the structure of the Red Hat Linux file system, to the finer points of system security and authentication control, we hope you will find this book to be a valuable resource.

This guide is for you if you want to learn a bit more about how your Red Hat Linux system works. Topics that you can explore within this manual include the following:

- The file system structure
- The boot process
- The X Windowing System
- Security issues
- Network services

1. Changes To This Manual

This manual has been reorganized for clarity and updated for the latest features of Red Hat Linux 8.0. Some of the changes include:

A New Boot Loaders Chapter

The GRUB chapter has been revised and expanded to include LILO.

An Updated Apache HTTP Server Chapter

There is now a guide for migrating from version 1.3 to version 2.0 of the Apache HTTP Server. Also, the list of server configuration options has been updated. Special thanks to **Gary Benson** and **Joe Orton** for his hard work on the Apache HTTP Server migration guide.

Updated LDAP Chapter

The LDAP chapter has been cleaned up and reorganized.

Updated iptables Chapter

The `iptables` chapter has been clarified and reorganized.

Updated Tripwire Chapter

The Tripwire chapter has been clarified and reorganized (and even has a fancy new illustration ;-).

Before reading this guide, you should be familiar with the contents of the *Official Red Hat Linux Installation Guide* concerning installation issues, the *Official Red Hat Linux Getting Started Guide* for basic Linux concepts and the *Official Red Hat Linux Customization Guide* for general customization instructions. The *Official Red Hat Linux Reference Guide* contains information about advanced topics that may not affect every user, depending upon how they use their Red Hat Linux system.

HTML and PDF versions of all Official Red Hat Linux manuals are available online at <http://www.redhat.com/docs>.

**Note**

Although this manual reflects the most current information possible, you should read the Red Hat Linux Release Notes for information that may not have been available prior to our documentation being finalized. The Release Notes can be found on the Red Hat Linux CD #1 and online at the following URL:

<http://www.redhat.com/docs/manuals/linux>

2. Finding Appropriate Documentation

You need documentation that is appropriate to your level of Linux expertise. Otherwise, you might feel overwhelmed or not find the necessary information to answer your questions. The *Official Red Hat Linux Reference Guide* deals with the more technical aspects and options of your Red Hat Linux system. This section will help you decide whether to look in this manual for the information you need or consider other Red Hat Linux manuals, including online sources, in your search.

Three different categories of people use Red Hat Linux, and each of these categories require different sets of documentation and informative sources. To help you figure out where you should start, determine your own experience level:

New to Linux

This type of user has never used any Linux (or Linux-like) operating system before or has had only limited exposure to Linux. They may or may not have experience using other operating systems (such as Windows). Is this you? If so, skip ahead to Section 2.1.

Some Linux Experience

This type of user has installed and successfully used Linux (but not Red Hat Linux) before or may have equivalent experience with other Linux-like operating systems. Does this describe you? If so, turn to Section 2.2.

Experienced User

This type of user has installed and successfully used Red Hat Linux before. If this describes you, turn to Section 2.3.

2.1. Documentation For First-Time Linux Users

For someone new to Linux, the amount of information available on any particular subject, such as printing, starting up the system or partitioning your hard drive, can be overwhelming. It helps to initially step back and gain a decent base of information centered around how Linux works before tackling these kinds of advanced issues.

Your first goal should be to obtain some useful documentation. This cannot be stressed enough. Without documentation, you will only become frustrated at your inability to get your Red Hat Linux system working the way you want.

You should acquire the following types of Linux documentation:

- *A brief history of Linux* — Many aspects of Linux are the way they are because of historical precedent. The Linux culture is also based on past events, needs or requirements. A basic understanding of the history of Linux will help you figure out how to solve many potential problems before you actually see them.

- *An explanation of how Linux works* — While delving into the most arcane aspects of the Linux kernel is not necessary, it is a good idea to know something about how Linux is put together. This is particularly important if you have been working with other operating systems, as some of the assumptions you currently hold about how computers work may not transfer from that operating system to Linux.
- *An introductory command overview (with examples)* — This is probably the most important thing to look for in Linux documentation. The underlying design philosophy for Linux is that it's better to use many small commands connected together in different ways than it is to have a few large (and complex) commands that do the whole job themselves. Without examples that illustrate this approach to doing things, you may find yourself intimidated by the sheer number of commands available on your Red Hat Linux system.

Keep in mind that you do not have to memorize all of the available Linux commands. Different techniques exist to help you find the specific command you need to accomplish a task. You need only know the general way in which Linux functions, what you need to accomplish, and how to access the tool that will give you the exact instructions you need to execute the command.

The *Official Red Hat Linux Installation Guide* is an excellent reference for helping you get your Red Hat Linux system successfully installed and initially configured. The *Official Red Hat Linux Getting Started Guide* covers the history of Linux, basic system commands, GNOME, KDE, RPM, and many other fundamental concepts. You should start with these two books and use them to build the base of your Red Hat Linux knowledge. Before long, more complicated concepts will begin to make sense because you already grasp the general ideas.

Beyond reading Red Hat Linux manuals, several other excellent documentation resources are available for little or no cost:

2.1.1. Introduction to Linux Websites

- <http://www.redhat.com> — On the Red Hat website, you will find links to the Linux Documentation Project (LDP), online versions of the Red Hat Linux manuals, FAQs (Frequently Asked Questions), a database which can help you find a Linux Users Group near you, technical information in the Red Hat Support Knowledge Base, and more.
- <http://www.linuxheadquarters.com> — The Linux Headquarters website features easy to follow, step-by-step guides for a variety of Linux tasks.

2.1.2. Introduction to Linux Newsgroups

You can participate in newsgroups by watching the discussions of others attempting to solve problems, or by actively asking or answering questions. Experienced Linux users are known to be extremely helpful when trying to assist new users with various Linux issues — especially if you are posing your questions in the right venue. If you do not have access to a news reader application, you can access this information via the web at <http://www.deja.com>. Dozens of Linux-related newsgroups exist, including the following:

- `linux.help` — A great place to get help from fellow Linux users.
- `linux.redhat` — This newsgroup primarily covers Red Hat Linux-specific issues.
- `linux.redhat.install` — Pose installation questions to this newsgroup or search it to see how others solved similar problems.
- `linux.redhat.misc` — Questions or requests for help that do not really fit into traditional categories go here.
- `linux.redhat.rpm` — A good place to go if you are having trouble using **RPM** to accomplish particular objectives.

2.1.3. Beginning Linux Books

- *Red Hat Linux for Dummies, 2nd Edition* by Jon "maddog" Hall; IDG
- *Special Edition Using Red Hat Linux* by Alan Simpson, John Ray and Neal Jamison; Que
- *Running Linux* by Matt Welsh and Lar Kaufman; O'Reilly & Associates
- *Red Hat Linux 7 Unleashed* by William Ball and David Pitts; Sams

The books suggested here are excellent primary sources of information for basic knowledge about a Red Hat Linux system. For more in-depth information concerning the various topics discussed throughout this book, many of the chapters list specific book titles, usually in an *Additional Resources* area.

2.2. For the More Experienced

If you have used other Linux distributions, you probably already have a basic grasp of the most frequently used commands. You may have installed your own Linux system, and maybe you have even downloaded and built software you found on the Internet. After installing Linux, however, configuration issues can be very confusing.

The *Official Red Hat Linux Customization Guide* is designed to help explain the various ways your Red Hat Linux system can be configured to meet specific objectives. Use this manual to learn about specific configuration options and how to put them into effect.

When you are installing software that is not covered in the *Official Red Hat Linux Customization Guide*, it is often helpful to see what other people in similar circumstances have done. HOWTO documents from the Linux Documentation Project, available at <http://www.redhat.com/mirrors/LDP/HOWTO/HOWTO-INDEX/howtos.html>, document particular aspects of Linux, from low-level kernel esoteric changes to using Linux for amateur radio station work.

2.3. Documentation for Linux Gurus

If you are a long-time Red Hat Linux user, you probably already know that one of the best ways to understand a particular program is to read its source code and/or configuration files. A major advantage of Red Hat Linux is the availability of the source code for anyone to read.

Obviously, not everyone is a C programmer, so the source code may not be helpful for you. However, if you have the knowledge and skills necessary to read it, the source code holds all of the answers.

3. Document Conventions

When you read this manual, you will see that certain words are represented in different fonts, typefaces, sizes, and weights. This highlighting is systematic; different words are represented in the same style to indicate their inclusion in a specific category. The types of words that are represented this way include the following:

command

Linux commands (and other operating system commands, when used) are represented this way. This style should indicate to you that you can type the word or phrase on the command line and press [Enter] to invoke a command. Sometimes a command contains words that would be

displayed in a different style on their own (such as filenames). In these cases, they are considered to be part of the command, so the entire phrase will be displayed as a command. For example:

Use the `cat testfile` command to view the contents of a file, named `testfile`, in the current working directory.

filename

Filenames, directory names, paths, and RPM package names are represented this way. This style should indicate that a particular file or directory exists by that name on your Red Hat Linux system. Examples:

The `.bashrc` file in your home directory contains bash shell definitions and aliases for your own use.

The `/etc/fstab` file contains information about different system devices and filesystems.

Install the `webalizer` RPM if you want to use a Web server log file analysis program.

application

This style should indicate to you that the program named is an end-user application (as opposed to system software). For example:

Use **Mozilla** to browse the Web.

[key]

A key on the keyboard is shown in this style. For example:

To use [Tab] completion, type in a character and then press the [Tab] key. Your terminal will display the list of files in the directory that start with that letter.

[key]-[combination]

A combination of keystrokes is represented in this way. For example:

The [Ctrl]-[Alt]-[Backspace] key combination will exit your graphical session and return you to the graphical login screen or the console.

text found on a GUI interface

A title, word, or phrase found on a GUI interface screen or window will be shown in this style. When you see text shown in this style, it is being used to identify a particular GUI screen or an element on a GUI screen (such as text associated with a checkbox or field). Example:

Select the **Require Password** checkbox if you would like your screensaver to require a password before stopping.

top level of a menu on a GUI screen or window

When you see a word in this style, it indicates that the word is the top level of a pulldown menu. If you click on the word on the GUI screen, the rest of the menu should appear. For example:

Under **File** on a GNOME terminal, you will see the **New Tab** option that allows you to open multiple shell prompts in the same window.

If you need to type in a sequence of commands from a GUI menu, they will be shown like the following example:

Go to **Main Menu Button** (on the Panel) => **Programming** => **Emacs** to start the **Emacs** text editor.

button on a GUI screen or window

This style indicates that the text will be found on a clickable button on a GUI screen. For example:
Click on the **Back** button to return to the webpage you last viewed.

computer output

When you see text in this style, it indicates text displayed by the computer on the command line. You will see responses to commands you typed in, error messages, and interactive prompts for your input during scripts or programs shown this way. For example:

Use the `ls` command to display the contents of a directory:

```
$ ls
Desktop          about.html      logs           paulwesterberg.png
Mail             backupfiles    mail           reports
```

The output returned in response to the command (in this case, the contents of the directory) is shown in this style.

prompt

A prompt, which is a computer's way of signifying that it is ready for you to input something, will be shown in this style. Examples:

```
$
#
[stephen@maturin stephen]$
leopard login:
```

user input

Text that the user has to type, either on the command line, or into a text box on a GUI screen, is displayed in this style. In the following example, **text** is displayed in this style:

To boot your system into the text based installation program, you will need to type in the **text** command at the `boot:` prompt.

Additionally, we use several different strategies to draw your attention to certain pieces of information. In order of how critical the information is to your system, these items will be marked as note, tip, important, caution, or a warning. For example:

Note

Remember that Linux is case sensitive. In other words, a rose is not a ROSE is not a rOsE.

Tip

The directory `/usr/share/doc` contains additional documentation for packages installed on your system.

**Important**

If you modify the DHCP configuration file, the changes will not take effect until you restart the DHCP daemon.

**Caution**

Do not perform routine tasks as root — use a regular user account unless you need to use the root account for system administration tasks.

**Warning**

If you choose not to partition manually, a server installation will remove all existing partitions on all installed hard drives. Do not choose this installation class unless you are sure you have no data you need to save.

4. Using the Mouse

Red Hat Linux is designed to use a three-button mouse. If you have a two-button mouse, you should have selected three-button emulation during the installation process. If you're using three-button emulation, pressing both mouse buttons at the same time equates to pressing the missing third (middle) button.

In this document, if you are instructed to click with the mouse on something, that means click the left mouse button. If you need to use the middle or right mouse button, that will be explicitly stated. (This will be reversed if you've configured your mouse to be used by a left handed person.)

The phrase "drag and drop" may be familiar to you. If you're instructed to drag and drop an item on your GUI desktop, click on something and hold the mouse button down. While continuing to hold down the mouse button, drag the item by moving the mouse to a new location. When you've reached the desired location, release the mouse button to drop the item.

5. Copying and Pasting Text With X

Copying and pasting text is easy using your mouse and the X Window System. To copy text, simply click and drag your mouse over the text to highlight it. To paste the text somewhere, click the middle mouse button in the spot where the text should be placed.

6. More to Come

The *Official Red Hat Linux Reference Guide* is part of Red Hat's commitment to provide useful and timely support to Red Hat Linux users. Future editions will feature expanded information on changes to system structure and organization, new and powerful security tools, and other resources to help you extend the power of your Red Hat Linux system — and your ability to use it.

That's where you can help.

6.1. We Need Feedback!

If you find an error in the *Official Red Hat Linux Reference Guide*, or if you have thought of a way to make this manual better, we'd love to hear from you! Please submit a report in Bugzilla (<http://bugzilla.redhat.com/bugzilla>) against the component *rhl-rg*.

Be sure to mention the manual's identifier:

```
rhl-rg (EN) -8.0-Print-RHI (2002-08-14T22:29-0400)
```

If you mention the manual's identifier, we will know exactly which version of the guide you have.

If you have a suggestion for improving the documentation, try to be as specific as possible when describing it. If you have found an error, please include the section number and some of the surrounding text so we can find it easily.

7. Sign Up for Support

If you have an official edition of Red Hat Linux 8.0, please remember to sign up for the benefits you are entitled to as a Red Hat customer.

You will be entitled to any or all of the following benefits, depending upon the Official Red Hat Linux product you purchased:

- Official Red Hat support — Get help with your installation questions from Red Hat, Inc.'s support team.
- Red Hat Network — Easily update your packages and receive security notices that are customized for your system. Go to <http://rhn.redhat.com> for more details.
- *Under the Brim: The Official Red Hat E-Newsletter* — Every month, get the latest news and product information directly from Red Hat.

To sign up, go to <http://www.redhat.com/apps/activate/>. You will find your Product ID on a black, red, and white card in your Official Red Hat Linux box.

To read more about technical support for Official Red Hat Linux, refer to the *Getting Technical Support* Appendix in the *Official Red Hat Linux Installation Guide*.

Good luck, and thank you for choosing Red Hat Linux!

The Red Hat Documentation Team

System Reference

File System Structure

1.1. Why Share a Common Structure?

An operating system's file system structure is its most basic level of organization. Almost all of the ways an operating system interacts with its users, applications, and security model are dependent upon the way it stores its files on a storage device. It is crucial for a variety of reasons that users, as well as programs, be able to refer to a common guideline to know where to read and write files.

A file system can be seen in terms of two different logical categories of files:

- Shareable vs. unshareable files
- Variable vs. static files

Shareable files are those that can be accessed by various hosts; *unshareable* files are not available to any other hosts. *Variable* files can change at any time without any intervention; *static* files, such as read-only documentation and binaries, do not change without an action from the system administrator or an agent that the system administrator has placed in motion to accomplish that task.

The reason for looking at files in this way is to help you understand the type of permissions given to the directory that holds them. The way in which the operating system and its users need to use the files determines the directory where those files should be placed, whether the directory is mounted read-only or read-write, and the level of access allowed on each file. The top level of this organization is crucial, as the access to the underlying directories can be restricted or security problems may manifest themselves if the top level is left disorganized or without a widely-used structure.

However, simply having a structure does not mean very much unless it is a standard. Competing structures can actually cause more problems than they fix. Because of this, Red Hat has chosen the the most widely-used file system structure and extended it only slightly to accommodate special files used within Red Hat Linux.

1.2. Overview of File System Hierarchy Standard (FHS)

Red Hat is committed to the *Filesystem Hierarchy Standard (FHS)*, a collaborative document that defines the names and locations of many files and directories. We will continue to track and follow the standard to keep Red Hat Linux FHS-compliant.

The current FHS document is the authoritative reference to any FHS-compliant file system, but the standard leaves many areas undefined or extensible. In this section, we provide an overview of the standard and a description of the parts of the file system not covered by the standard.

The complete standard is available at:

<http://www.pathname.com/fhs>

Compliance with the standard means many things, but the two most important are compatibility with other compliant systems and the ability to mount a `/usr` partition as read-only because it contains common executables and is not meant to be changed by users. Since the `/usr` directory is mounted read-only, it can be mounted from the CD-ROM or from another machine via a read-only NFS mount.

1.2.1. FHS Organization

The directories and files noted here are a small subset of those specified by the FHS document. Check the latest FHS document for the most complete information.

1.2.1.1. The `/dev` Directory

The `/dev` directory contains file system entries which represent devices that are attached to the system. These files are essential for the system to function properly.

1.2.1.2. The `/etc` Directory

The `/etc` directory is reserved for configuration files that are local to your machine. No binaries are to be put in `/etc`. Any binaries that were formerly put in `/etc` should now go into `/sbin` or possibly `/bin`.

The `X11` and `skel` directories are subdirectories of the `/etc` directory:

```
/etc
|- X11
|- skel
```

The `X11` directory is for X11 configuration files such as `XF86Config`. The `skel` directory is for "skeleton" user files, which are used to populate a home directory when a user is first created.

1.2.1.3. The `/lib` Directory

The `/lib` directory should contain only those libraries that are needed to execute the binaries in `/bin` and `/sbin`. These shared library images are particularly important for booting the system and executing commands within the root file system.

1.2.1.4. The `/mnt` Directory

The `/mnt` directory is for temporarily mounted file systems, such as CD-ROMs and floppy disks.

1.2.1.5. The `/opt` Directory

The `/opt` directory provides an area for large, static application software packages to be stored.

For packages that wish to avoid putting their files throughout the file system, `/opt` provides a logical and predictable organizational system under that package's directory. This gives the system administrator an easy way to determine the role of each file within a particular package.

For example, if `sample` is the name of a particular software package located within `/opt`, then all of its files could be placed within directories inside `/opt/sample`, such as `/opt/sample/bin` for binaries and `/opt/sample/man` for manual pages.

Large packages that encompass many different sub-packages, each of which accomplish a particular task, also go within `/opt`, giving that large package a standardized way to organize itself. In this way, our `sample` package may have different tools that each go in their own sub-directories, such as `/opt/sample/tool1` and `/opt/sample/tool2`, each of which can have their own `bin`, `man`, and other similar directories.

1.2.1.6. The `/proc` Directory

The `/proc` directory contains special "files" that either extract information from or send information to the kernel.

Due to the great variety of data available within `/proc` and the many ways this directory can be used to communicate with the kernel, an entire chapter has been devoted to the subject. For more information, please see Chapter 2.

1.2.1.7. The `/sbin` Directory

The `/sbin` directory is for executables used only by the root user. The executables in `/sbin` are only used to boot and mount `/usr` and perform system recovery operations. The FHS says:

"`/sbin` typically contains files essential for booting the system in addition to the binaries in `/bin`. Anything executed after `/usr` is known to be mounted (when there are no problems) should be placed in `/usr/sbin`. Local-only system administration binaries should be placed into `/usr/local/sbin`."

At a minimum, the following programs should be in `/sbin`:

```
arp, clock,
getty, halt,
init, fdisk,
fsck.*, grub,
ifconfig, lilo,
mkfs.*, mkswap,
reboot, route,
shutdown, swapon,
swapon, update
```

1.2.1.8. The `/usr` Directory

The `/usr` directory is for files that can be shared across a whole site. The `/usr` directory usually has its own partition, and it should be mountable read-only. At minimum, the following directories should be subdirectories of `/usr`:

```
/usr
|- bin
|- dict
|- doc
|- etc
|- games
|- include
|- kerberos
|- lib
|- libexec
|- local
|- sbin
|- share
|- src
|- tmp -> ../var/tmp
|- X11R6
```

The `bin` directory contains executables, `dict` contains non-FHS compliant documentation pages, `etc` contains system-wide configuration files, `games` is for games, `include` contains C header files, `kerberos` contains binaries and much more for Kerberos, and `lib` contains object files and libraries

that are not designed to be directly utilized by users or shell scripts. The `libexec` directory contains small helper programs called by other programs, `sbin` is for system administration binaries (those that do not belong in `/sbin`), `share` contains files that are not architecture-specific, `src` is for source code, and `X11R6` is for the X Window System (**XFree86** on Red Hat Linux).

1.2.1.9. The `/usr/local` Directory

The FHS says:

"The `/usr/local` hierarchy is for use by the system administrator when installing software locally. It needs to be safe from being overwritten when the system software is updated. It may be used for programs and data that are shareable among a group of hosts, but not found in `/usr`."

The `/usr/local` directory is similar in structure to the `/usr` directory. It has the following subdirectories, which are similar in purpose to those in the `/usr` directory:

```
/usr/local
|- bin
|- doc
|- etc
|- games
|- include
|- lib
|- libexec
|- sbin
|- share
|- src
```

1.2.1.10. The `/var` Directory

Since the FHS requires that you be able to mount `/usr` read-only, any programs that write log files or need `spool` or `lock` directories should write them to the `/var` directory. The FHS states `/var` is for:

"...variable data files. This includes `spool` directories and files, administrative and logging data, and transient and temporary files."

Below are some of the directories which should be subdirectories of `/var`:

```
/var
|- account
|- arpwatch
|- cache
|- crash
|- db
|- empty
|- ftp
|- gdm
|- kerberos
|- lib
|- local
|- lock
|- log
|- mail -> spool/mail
|- mailman
```

```

|- named
|- nis
|- opt
|- preserve
|- run
+- spool
    |- anacron
    |- at
    |- cron
    |- fax
    |- lpd
    |- mail
    |- mqueue
    |- news
    |- rwho
    |- samba
    |- sirnpull
    |- squid
    |- up2date
    |- uucp
    |- uucppublic
    |- vbox
    |- voice
|- tmp
|- tux
|- www
|- yp

```

System log files such as `messages` and `lastlog` go in `/var/log`. The `/var/lib/rpm` directory also contains the RPM system databases. Lock files go in `/var/lock`, usually in directories particular for the program using the file. The `/var/spool` directory has subdirectories for various systems that need to store data files.

1.2.2. `/usr/local` in Red Hat Linux

In Red Hat Linux, the intended use for `/usr/local` is slightly different from that specified by the FHS. The FHS says that `/usr/local` should be where you store software that is to remain safe from system software upgrades. Since system upgrades from Red Hat are done safely with the `rpm` command and graphical **Package Management Tool** application, you do not need to protect files by putting them in `/usr/local`. Instead, we recommend you use `/usr/local` for software that is local to your machine.

For instance, say you have mounted `/usr` via read-only NFS from a host named `jake`. If there is a package or program you would like to install, but you are not allowed to write to `jake`, you should install it under `/usr/local`. Later perhaps, if you have managed to convince the system administrator of `jake` to install the program on `/usr`, you can uninstall it from `/usr/local`.

1.3. Special File Locations

Red Hat extends the FHS structure slightly to accommodate special files used by Red Hat Linux.

Most files pertaining to the *Red Hat Package Manager (RPM)* are kept in the `/var/lib/rpm/` directory. For more information on RPM see the chapter titled *Package Management with RPM* in the *Official Red Hat Linux Customization Guide*.

The `/var/spool/updates/` directory contains files used by **Red Hat Update Agent**, including RPM header information for the system. This location may also be used to temporarily store RPMs downloaded while updating your system. For more information on Red Hat Network, see the Red Hat Network website at <https://rhn.redhat.com/>.

Another location specific to Red Hat Linux is the `/etc/sysconfig/` directory. This directory stores a variety of configuration information. Many scripts that run at boot time use the files in this directory. See Section 3.7 for more information on what is within this directory and the role these files play in the boot process.

Finally, one more directory worth noting is the `/initrd/` directory. It is empty, but is used as a critical mount point during the boot process.

**Warning**

Do not remove the `/initrd/` directory for any reason. Removing this directory will cause your system to fail to boot with a kernel panic error message.

The `proc` File System

The Linux kernel has two primary functions: to control access to physical devices on the computer and to schedule when and how processes interact with these devices. The `/proc/` directory contains a hierarchy of special files which represent the current state of the kernel — allowing applications and users to peer into the kernel's view of the system.

Within the `/proc/` directory, one can find a wealth of information about the system hardware and any processes currently running. In addition, some of the files within the `/proc/` directory tree can be manipulated by users and applications to communicate configuration changes to the kernel.

2.1. A Virtual File System

Under Linux, all data are stored as files. Most users are familiar with the two primary types of files: text and binary. But the `/proc/` directory contains another type of file called a *virtual file*. It is for this reason that `/proc/` is often referred to as a *virtual file system*.

These virtual files have unique qualities. Most of them are listed as zero bytes in size and yet when one is viewed, it can contain a large amount of information. In addition, most of the time and date settings on virtual files reflect the current time and date, indicative of the fact they constantly changing.

Virtual files such as `interrupts`, `/proc/meminfo`, `/proc/mounts`, and `/proc/partitions` provide an up-to-the-moment glimpse of the system's hardware. Others, like `/proc/filesystems` and the `/proc/sys/` directory provide system configuration information and interfaces.

For organizational purposes, files containing information on a similar topic are grouped into virtual directories and sub-directories. For instance, `/proc/ide/` contains information for all physical IDE devices. Likewise, process directories contain information about each running process on the system.

2.1.1. Viewing Virtual Files

By using the `cat`, `more`, or `less` commands on files within the `/proc/` directory, you can immediately access an enormous amount of information about the system. For example, if you want to see what sort of CPU your computer has, type `cat /proc/cpuinfo` and you will see something similar to the following:

```
processor : 0
vendor_id : AuthenticAMD
cpu family : 5
model : 9
model name : AMD-K6(tm) 3D+ Processor
stepping : 1
cpu MHz : 400.919
cache size : 256 KB
fdiv_bug : no
hlt_bug : no
f00f_bug : no
coma_bug : no
fpu : yes
fpu_exception : yes
cpuid level : 1
wp : yes
flags : fpu vme de pse tsc msr mce cx8 pge mmx syscall 3dnow k6_mtrr
bogomips : 799.53
```

When viewing different virtual files in the `/proc/` file system, you will notice some of the information is easily understandable while some is not human-readable. This is in part why utilities exist to pull data from virtual files and display it in a useful way. Some examples of such applications are `lspci`, `apm`, `free`, and `top`.

Note

Some of the virtual files in the `/proc/` directory are only readable by the root user.

2.1.2. Changing Virtual Files

As a general rule, most virtual files within the `/proc/` directory are read only. However, some can be used to adjust settings in the kernel. This is especially true for files in the `/proc/sys/` subdirectory.

To change the value of a virtual file, use the `echo` command and a `>` symbol to redirect the new value to the file. For instance, to change your hostname on the fly, you can type:

```
echo bob.subgenius.com > /proc/sys/kernel/hostname
```

Other files act as binary or boolean switches. For instance, if you type `cat /proc/sys/net/ipv4/ip_forward`, you will see either a 0 or a 1. A 0 indicates the kernel is not forwarding network packets. By using the `echo` command to change the value of the `ip_forward` file to 1, you can immediately turn packet forwarding on.

Tip

Another command used to alter settings in the `/proc/sys/` subdirectory is `/sbin/sysctl`. For more information on this command, see Section 2.4

For a listing of some of the kernel configuration files available in the `/proc/sys/`, see Section 2.3.9.

2.2. Top-level Files in the `proc` Filesystem

Below is a list of some of the more useful virtual files in the top-level of the `/proc/` directory.

Note

In most cases, the content of files listed in this section will not be the same on your machine. This is because much of the information pertains to the hardware on which you are running Red Hat Linux.

2.2.1. `/proc/apm`

This file provides information about the state of the *Advanced Power Management (APM)* system and is used by the `apm` command. If the system with no battery is connected to an AC power source, this virtual file looks similar to this:

```
1.16 1.2 0x07 0x01 0xff 0x80 -1% -1 ?
```

Running the `apm -v` command on such a system results in output similar to this:

```
APM BIOS 1.2 (kernel driver 1.16)
AC on-line, no system battery
```

For systems which do not use a battery as a power source, `apm` is able do little more than put the machine in standby mode. The `apm` command is much more useful on laptops. For example, the following output is from the command `cat /proc/apm` on a laptop running Red Hat Linux while plugged into a power outlet:

```
1.16 1.2 0x03 0x01 0x03 0x09 100% -1 ?
```

When the same laptop is unplugged from its power source for a few minutes, the contents of the `apm` file change to something like this:

```
1.16 1.2 0x03 0x00 0x00 0x01 99% 1792 min
```

The `apm -v` command will now yield more useful data, such as the following:

```
APM BIOS 1.2 (kernel driver 1.16)
AC off-line, battery status high: 99% (1 day, 5:52)
```

2.2.2. `/proc/cmdline`

This file shows the parameters passed to the kernel at the time it is started. A sample `/proc/cmdline` file looks like this:

```
ro root=/dev/hda2
```

This tell us the kernel is mounted read-only — signified by (`ro`) — off of the second partition on the first IDE device (`/dev/hda2`).

2.2.3. `/proc/cpuinfo`

This virtual file identifies the type of processor used by your system. The following is an example of the output you would typically see from `/proc/cpuinfo`:

```
processor       : 0
vendor_id      : AuthenticAMD
cpu family     : 5
model          : 9
model name     : AMD-K6(tm) 3D+ Processor
stepping      : 1
cpu MHz       : 400.919
cache size    : 256 KB
fdiv_bug      : no
hlt_bug       : no
f00f_bug      : no
coma_bug      : no
fpu           : yes
fpu_exception : yes
cpuid level   : 1
wp            : yes
flags         : fpu vme de pse tsc msr mce cx8 pge mmx syscall 3dnow k6_mtrr
bogomips     : 799.53
```

- `processor` — Provides each processor with an identifying number. If you only have one processor, you will only see a 0.
- `cpu family` — Authoritatively tells you the type of processor you have in the system. If your computer is an Intel-based system, simply place the number in front of "86" to determine the value. This is particularly helpful if you are wondering about the architecture of an older system such as the 586, 486, or 386. Because some RPM packages are compiled for each of these particular architectures, this value enables you determine which package to install.
- `model name` — Gives you the common name of the processor, including its project name.
- `cpu MHz` — Shows the precise speed in megahertz for the processor to the thousandth decimal point.
- `cache size` — Tells you the amount of level 2 memory cache available to the processor.
- `flags` — Defines a number of different qualities about the processor, such as the presence of a floating point unit (FPU) and the ability to process MMX instructions.

2.2.4. `/proc/devices`

This file displays the various character and block devices currently configured for use with the kernel. It does not include devices whose modules are not loaded into the kernel. Below is a sample output from this virtual file:

Character devices:

```

1 mem
2 pty
3 tty
4 ttyS
5 cua
7 vcs
10 misc
14 sound
29 fb
36 netlink
128 ptm
129 ptm
136 pts
137 pts
162 raw
254 iscsictl
```

Block devices:

```

1 ramdisk
2 fd
3 ide0
9 md
22 ide1
```

The output from `/proc/devices` includes the major number and name of the device and is broken into two major sections: `Character devices` and `Block devices`.

Character devices are similar to *block devices*, except for two basic differences.

Block devices have a buffer available, allowing them to order requests before dealing with them. This is important for devices designed to store information — such as hard drives — because the ability to order the information before writing it to the device allows it to be placed in more efficient order. Character devices do not require buffering.

The other difference is that block devices can send and receive information in blocks of a size configured per device. Character devices send data with no preconfigured size.

For more information about devices see `/usr/src/linux-2.4/Documentation/devices.txt`.

2.2.5. `/proc/dma`

This file contains a list of the registered ISA direct memory access (DMA) channels in use. A sample `/proc/dma` files looks like this:

```
4: cascade
```

2.2.6. `/proc/execd domains`

This file lists the *execution domains* currently supported by the Linux kernel, along with the range of personalities they support.

```
0-0 Linux [kernel]
```

Think of execution domains as the "personality" for a particular operating system. Because other binary formats, such as Solaris, UnixWare, and FreeBSD, can be used with Linux, programmers can change the way the operating system treats particular system calls from these binaries by changing the personality of the task. Except for the `PER_LINUX` execution domain, different personalities can be implemented as dynamically loadable modules.

2.2.7. `/proc/fb`

This file contains a list of frame buffer devices, with the frame buffer device number and the driver that controls it. Typical output of `/proc/fb` for systems which contain frame buffer devices looks similar to this:

```
0 VESA VGA
```

2.2.8. `/proc/filesystems`

This file displays a list of the file system types currently supported by the kernel. Sample output from a generic kernel's `/proc/filesystems` file looks similar to this:

```
nodev rootfs
nodev bdev
nodev proc
nodev sockfs
nodev tmpfs
nodev shm
nodev pipefs
  ext2
nodev ramfs
  iso9660
nodev devpts
  ext3
nodev autofs
nodev binfmt_misc
```

The first column signifies whether the file system is mounted on a block device. Those beginning with `nodev` are not mounted on a device. The second column lists the name of the file systems supported.

The `mount` command cycles through these file systems when one is not specified as an argument.

2.2.9. `/proc/interrupts`

This file records the number of interrupts per IRQ on the x86 architecture. A standard `/proc/interrupts` looks similar to this:

```

CPU0
0: 80448940      XT-PIC timer
1: 174412       XT-PIC keyboard
2: 0            XT-PIC cascade
8: 1           XT-PIC rtc
10: 410964     XT-PIC eth0
12: 60330      XT-PIC PS/2 Mouse
14: 1314121    XT-PIC ide0
15: 5195422    XT-PIC ide1
NMI: 0
ERR: 0

```

For a multi-processor machine, this file may look slightly different:

```

CPU0      CPU1
0: 1366814704      0      XT-PIC timer
1: 128            340     IO-APIC-edge keyboard
2: 0             0      XT-PIC cascade
8: 0             1      IO-APIC-edge rtc
12: 5323         5793    IO-APIC-edge PS/2 Mouse
13: 1            0      XT-PIC fpu
16: 11184294     15940594 IO-APIC-level Intel EtherExpress Pro 10/100 Ethernet
20: 8450043     11120093 IO-APIC-level megaraid
30: 10432        10722    IO-APIC-level aic7xxx
31: 23          22     IO-APIC-level aic7xxx
NMI: 0
ERR: 0

```

The first column refers to the IRQ number. Each CPU in the system has its own column and its own number of interrupts per IRQ. The next column reports the type of interrupt, and the last column contains the name of the device that is located at that IRQ.

Each of the types of interrupts seen in this file, which are architecture-specific, mean something a little different. For x86 machines, the following values are common:

- `XT-PIC` — This is the old AT computer interrupts.
- `IO-APIC-edge` — The voltage signal on this interrupt transitions from low to high, creating an *edge*, where the interrupt occurs and is only signaled once. This kind of interrupt, as well as the `IO-APIC-level` interrupt, are only seen on systems with processors from the 586 family and higher.
- `IO-APIC-level` — Generates interrupts when its voltage signal goes high until the signal goes low again.

2.2.10. `/proc/iomem`

This file shows you the current map of the system's memory for each physical device:

```
00000000-0009fbff : System RAM
0009fc00-0009ffff : reserved
000a0000-000bffff : Video RAM area
000c0000-000c7fff : Video ROM
000f0000-000fffff : System ROM
00100000-07ffffff : System RAM
    00100000-00291ba8 : Kernel code
    00291ba9-002e09cb : Kernel data
e0000000-e3ffffff : VIA Technologies, Inc. VT82C597 [Apollo VP3]
e4000000-e7ffffff : PCI Bus #01
    e4000000-e4003fff : Matrox Graphics, Inc. MGA G200 AGP
    e5000000-e57ffffff : Matrox Graphics, Inc. MGA G200 AGP
e8000000-e8ffffff : PCI Bus #01
    e8000000-e8ffffff : Matrox Graphics, Inc. MGA G200 AGP
ea000000-ea00007f : Digital Equipment Corporation DECchip 21140 [FasterNet]
    ea000000-ea00007f : tulip
ffff0000-ffffffff : reserved
```

The first column displays the memory registers used by each of the different types of memory. The second column tells the kind of memory located within those registers. In particular, this column will tell you which memory registers are used by the kernel within the system RAM or, if you have multiple Ethernet ports on your NIC, the memory registers assigned for each port.

2.2.11. `/proc/ioports`

The output of `/proc/ioports` provides a list of currently registered port regions used for input or output communication with a device. This file can be quite long, with a beginning similar to this:

```
0000-001f : dma1
0020-003f : pic1
0040-005f : timer
0060-006f : keyboard
0070-007f : rtc
0080-008f : dma page reg
00a0-00bf : pic2
00c0-00df : dma2
00f0-00ff : fpu
0170-0177 : ide1
01f0-01f7 : ide0
02f8-02ff : serial(auto)
0376-0376 : ide1
03c0-03df : vga+
03f6-03f6 : ide0
03f8-03ff : serial(auto)
0cf8-0cff : PCI conf1
d000-dfff : PCI Bus #01
e000-e00f : VIA Technologies, Inc. Bus Master IDE
    e000-e007 : ide0
    e008-e00f : ide1
e800-e87f : Digital Equipment Corporation DECchip 21140 [FasterNet]
    e800-e87f : tulip
```

The first column gives the IO port address range reserved for the device listed in the second column.

2.2.12. `/proc/isapnp`

This file lists *Plug and Play (PnP)* cards in ISA slots on the system. This is most often seen with sound cards but may include any number of devices. A `/proc/isapnp` file with Soundblaster entry in it looks similar to this:

```
Card 1 'CTL0070:Creative ViBRA16C PnP' PnP version 1.0 Product version 1.0
Logical device 0 'CTL0001:Audio'
  Device is not active
  Active port 0x220,0x330,0x388
  Active IRQ 5 [0x2]
  Active DMA 1,5
  Resources 0
    Priority preferred
    Port 0x220-0x220, align 0x0, size 0x10, 16-bit address decoding
    Port 0x330-0x330, align 0x0, size 0x2, 16-bit address decoding
    Port 0x388-0x3f8, align 0x0, size 0x4, 16-bit address decoding
    IRQ 5 High-Edge
    DMA 1 8-bit byte-count compatible
    DMA 5 16-bit word-count compatible
  Alternate resources 0:1
    Priority acceptable
    Port 0x220-0x280, align 0x1f, size 0x10, 16-bit address decoding
    Port 0x300-0x330, align 0x2f, size 0x2, 16-bit address decoding
    Port 0x388-0x3f8, align 0x0, size 0x4, 16-bit address decoding
    IRQ 5,7,2/9,10 High-Edge
    DMA 1,3 8-bit byte-count compatible
    DMA 5,7 16-bit word-count compatible
```

This file can be quite long, depending on the number of devices displayed and their resource requirements.

Each card lists its name, PnP version number, and product version number. If the device is active and configured, this file will also reveal the port and IRQ numbers for the device. In addition, to ensure better compatibility, the card will specify preferred and acceptable values for a number of different parameters. The goal here is to allow the PnP cards to work around one another and avoid IRQ and port conflicts.

2.2.13. `/proc/kcore`

This file represents the physical memory of the system and is stored in the core file format. Unlike most `/proc/` files, `kcore` displays a size. This value is given in bytes and is equal to the size of physical memory (RAM) used plus 4KB.

The contents of this file are designed to be examined by a debugger, such as `gdb` and is not human readable.

Warning

Do not view the `/proc/kcore` virtual file. The contents of the file will scramble text output on the terminal. If you accidentally view this file, press [Ctrl]-[C] to stop the process then type `reset` to bring back the command line prompt.

2.2.14. `/proc/kmsg`

This file is used to hold messages generated by the kernel. These messages are then picked up by other programs, such as `/sbin/klogd`.

2.2.15. `/proc/ksyms`

This file holds the kernel exported symbol definitions used by the module tools to dynamically link and bind loadable modules.

```
e003def4 speedo_debug [eeepro100]
e003b04c eeepro100_init [eeepro100]
e00390c0 st_template [st]
e002104c RDINDOOR [megaraid]
e00210a4 callDone [megaraid]
e00226cc megaraid_detect [megaraid]
```

The first column lists the memory address for the kernel function, the second column refers to the name of the function, and the last column reveals the name of the loaded module.

2.2.16. `/proc/loadavg`

This file provides a look at load average on the processor over time and additional data used by `uptime` and other commands. A sample `/proc/loadavg` file looks similar to this:

```
0.20 0.18 0.12 1/80 11206
```

The first three columns measure CPU utilization of the last 1, 5, and 10 minute periods. The fourth column shows the number of currently running processes and the total number of processes. The last column displays the last process ID used.

2.2.17. `/proc/locks`

This files displays the files currently locked by the kernel. The content of this file contains internal kernel debugging data and can vary tremendously, depending on the use of the system. A sample `/proc/locks` file for a lightly loaded system looks similar to this:

```
1: FLOCK ADVISORY WRITE 807 03:05:308731 0 EOF c2a260c0 c025aa48 c2a26120
2: POSIX ADVISORY WRITE 708 03:05:308720 0 EOF c2a2611c c2a260c4 c025aa48
```

Each lock has its own line which starts with a unique number. The second column refers to the class of lock used, with `FLOCK` signifying the older-style UNIX file locks from a `flock` system call and `POSIX` representing the newer POSIX locks from the `lockf` system call.

The third column can have two values. `ADVISORY` means that the lock does not prevent other people from accessing the data; it only prevents other attempts to lock it. `MANDATORY` means that no other access to the data is permitted while the lock is held. The fourth column reveals whether the lock is allowing the holder `READ` or `WRITE` access to the file, and the fifth column shows the ID of the process holding the lock. The sixth column shows the ID of the file being locked, in the format of `MAJOR-DEVICE:MINOR-DEVICE:INODE-NUMBER`. The seventh column shows the start and end of the file's locked region. The remaining columns point to internal kernel data structures used for specialized debugging and can be ignored.

2.2.18. `/proc/mdstat`

This file contains the current information for multiple-disk, RAID configurations. If your system does not contain such a configuration, then your `/proc/mdstat` file will look similar to this:

```
Personalities :
read_ahead not set
unused devices: <none>
```

This file remains in the state above unless you create a software RAID or `md` device. In that case, you can view `/proc/mdstat` to give you a picture of what is currently happening with your `mdX` RAID devices.

The `/proc/mdstat` file below shows a system with its `md0` configured as a RAID 1 device. It is currently re-syncing the disks:

```
Personalities : [linear] [raid1]
read_ahead 1024 sectors
md0: active raid1 sda2[1] sdb2[0] 9940 blocks [2/2] [UU] resync=1% finish=12.3min
algorithm 2 [3/3] [UUU]
unused devices: <none>
```

2.2.19. `/proc/meminfo`

This is one of the more commonly used files in the `/proc/` directory, as it reports back plenty of valuable information about the current RAM usage on the system. A system with 256MB of RAM and 384MB of swap space will likely have a `/proc/meminfo` file similar to this one:

```

total:    used:    free:    shared:    buffers:    cached:
Mem: 261709824 253407232 8302592      0 120745984 48689152
Swap: 402997248      8192 402989056
MemTotal:      255576 kB
MemFree:       8108 kB
MemShared:     0 kB
Buffers:      117916 kB
Cached:       47548 kB
Active:       135300 kB
Inact_dirty:  29276 kB
Inact_clean:  888 kB
Inact_target: 0 kB
HighTotal:    0 kB
HighFree:     0 kB
LowTotal:     255576 kB
LowFree:      8108 kB
SwapTotal:    393552 kB
SwapFree:     393544 kB
```

Much of the information here is used by the `free`, `top`, and `ps` commands. In fact, the output of the `free` command is even similar in appearance to the contents and structure of `/proc/meminfo`. But by looking directly at `/proc/meminfo`, more details are revealed:

- `Mem` — Displays the current state of physical RAM in the system, including a full breakdown of total, used, free, shared, buffered, and cached memory utilization in bytes.
- `Swap` — Displays the total, used, and free amounts of swap space, in bytes.
- `MemTotal` — Total amount of physical RAM, in kilobytes.

- `MemFree` — The amount of physical RAM, in kilobytes, left unused by the system.
- `MemShared` — Unused with 2.4 and higher kernels but left in for compatibility with earlier kernel versions.
- `Buffers` — The amount of physical RAM, in kilobytes, used for file buffers.
- `Cached` — The amount of physical RAM, in kilobytes, used as cache memory.
- `Active` — The total amount of buffer or page cache memory, in kilobytes, that is in active use.
- `Inact_dirty` — The total amount of buffer or cache pages, in kilobytes, that might be free and available.
- `Inact_clean` — The total amount of buffer or cache pages in kilobytes that are definitely free and available.
- `Inact_target` — The net amount of allocations per second, in kilobytes, averaged over one minute.
- `HighTotal` and `HighFree` — The total and free amount of memory, respectively, that is not directly mapped into kernel space. The `HighTotal` value can vary based on the type of kernel used.
- `LowTotal` and `LowFree` — The total and free amount of memory, respectively, that is directly mapped into kernel space. The `LowTotal` value can vary based on the type of kernel used.
- `SwapTotal` — The total amount of swap available, in kilobytes.
- `SwapFree` — The total amount of swap free, in kilobytes.

2.2.20. `/proc/misc`

This file lists miscellaneous drivers registered on the miscellaneous major device, which is device number 10:

```
135 rtc
    1 psaux
134 apm_bios
```

The first column is the minor number of each device, and the second column shows the driver in use.

2.2.21. `/proc/modules`

This file displays a list of all modules loaded into the kernel. Its contents will vary based on the configuration and use of your system, but it should be organized in a similar manner to this sample `/proc/modules` file output:

```
ide-cd                27008    0 (autoclean)
cdrom                 28960    0 (autoclean) [ide-cd]
soundcore              4100    0 (autoclean)
agpgart               31072    0 (unused)
binfmt_misc           5956     1
iscsi                 32672    0 (unused)
scsi_mod              94424    1 [iscsi]
autofs                10628    0 (autoclean) (unused)
tulip                 48608    1
ext3                  60352    2
jbd                   39192    2 [ext3]
```

The first column contains the name of the module. The second column refers to the memory size of the module, in bytes. The third column tells you whether the module is currently loaded (1) or unloaded

(0). The final column states if the module can unload itself automatically after a period without use (`autoclean`) or if it is not being utilized (`unused`). Any module with a line containing a name listed in brackets (`[]`) tells you that this module depends upon another module to be present in order to function.

2.2.22. `/proc/mounts`

This file provides a quick list of all mounts in use by the system:

```
rootfs / rootfs rw 0 0
/dev/hda2 / ext3 rw 0 0
/proc /proc proc rw 0 0
/dev/hda1 /boot ext3 rw 0 0
none /dev/pts devpts rw 0 0
none /dev/shm tmpfs rw 0 0
none /proc/sys/fs/binfmt_misc binfmt_misc rw 0 0
```

The output found here is similar to contents of `/etc/mtab`, except that `/proc/mount` can be more current.

The first column specifies the device that is mounted, with the second column revealing the mount-point. The third column tells the file system type, and the fourth column tells you if it is mounted read-only (`ro`) or read-write (`rw`). The fifth and sixth columns are dummy values designed to match the format used in `/etc/mtab`.

2.2.23. `/proc/mtrr`

This file refers to the current Memory Type Range Registers (MTRRs) in use with the system. If your system's architecture supports MTRRs, your `mtrr` might look something like this:

```
reg00: base=0x00000000 ( 0MB), size= 64MB: write-back, count=1
```

MTRRs are used with Intel P6 family of processors (Pentium II and higher), and they are used to control processor access to memory ranges. When using a video card on a PCI or AGP bus, a properly configured `/proc/mtrr` file can increase performance over 150%.

Most of the time, this value is properly configured for you. For more information on MTRRs and manually configuring this file, please see <http://web1.linuxhq.com/kernel/v2.3/doc/mtrr.txt.html>.

2.2.24. `/proc/partitions`

Most of the information here is of little importance to the user, except for the following columns:

- `major` — The major number of the device with this partition. The major number in our example (3) corresponds with the block device `ide0` in `/proc/devices`.
- `minor` — The minor number of the device with this partition. This serves to separate the partitions into different physical devices and relates to the number at the end of the name of the partition.
- `#blocks` — Lists the number of physical disk blocks contained in a particular partition.
- `name` — The name of the partition.

2.2.25. `/proc/pci`

This file contains a full listing of every PCI device on your system. Depending on the number of PCI devices you have, `/proc/pci` can get rather long. An example from this file on a basic system looks similar to this:

```

Bus 0, device 0, function 0:
  Host bridge: Intel Corporation 440BX/ZX - 82443BX/ZX Host bridge (rev 3).
  Master Capable. Latency=64.
  Prefetchable 32 bit memory at 0xe4000000 [0xe7fffffff].
Bus 0, device 1, function 0:
  PCI bridge: Intel Corporation 440BX/ZX - 82443BX/ZX AGP bridge (rev 3).
  Master Capable. Latency=64. Min Gnt=128.
Bus 0, device 4, function 0:
  ISA bridge: Intel Corporation 82371AB PIIX4 ISA (rev 2).
Bus 0, device 4, function 1:
  IDE interface: Intel Corporation 82371AB PIIX4 IDE (rev 1).
  Master Capable. Latency=32.
  I/O at 0xd800 [0xd80f].
Bus 0, device 4, function 2:
  USB Controller: Intel Corporation 82371AB PIIX4 USB (rev 1).
  IRQ 5.
  Master Capable. Latency=32.
  I/O at 0xd400 [0xd41f].
Bus 0, device 4, function 3:
  Bridge: Intel Corporation 82371AB PIIX4 ACPI (rev 2).
  IRQ 9.
Bus 0, device 9, function 0:
  Ethernet controller: Lite-On Communications Inc LNE100TX (rev 33).
  IRQ 5.
  Master Capable. Latency=32.
  I/O at 0xd000 [0xd0ff].
  Non-prefetchable 32 bit memory at 0xe3000000 [0xe30000ff].
Bus 0, device 12, function 0:
  VGA compatible controller: S3 Inc. ViRGE/DX or /GX (rev 1).
  IRQ 11.
  Master Capable. Latency=32. Min Gnt=4.Max Lat=255.
  Non-prefetchable 32 bit memory at 0xdc000000 [0xdfffffff].

```

This output shows a list of all PCI devices, sorted in the order of bus, device, and function. Beyond providing the name and version of the device, this list also gives you detailed IRQ information so you can quickly look for conflicts.

Tip

To get a more readable version of this information, type:

```
lspci -vb
```

2.2.26. `/proc/slabinfo`

This file gives information about memory usage on the slab level. Linux kernels greater than 2.2 use *slab pools* to manage memory above the page level. Commonly used objects have their own slab pools. The following is a portion of a typical `/proc/slabinfo` virtual file:

```
slabinfo - version: 1.1
kmem_cache      64      68     112     2     2     1
nfs_write_data   0       0     384     0     0     1
nfs_read_data   0      160    384     0    16     1
nfs_page        0      200     96     0     5     1
ip_fib_hash     10     113     32     1     1     1
journal_head    51    7020     48     2    90     1
revoke_table    2      253     12     1     1     1
revoke_record   0       0     32     0     0     1
clip_arp_cache  0       0    128     0     0     1
ip_mrt_cache    0       0     96     0     0     1
```

The values in this file occur in the following order: cache name, number of active objects, number of total objects, size of the object, number of active slabs (blocks) of the objects, total number of slabs of the objects, and the number of pages per slab.

Note that *active* in this case means an object is in use. Therefore an active object is one that is in use, and an active slab is one that contains one or more active object.

2.2.27. `/proc/stat`

This file keeps track of a variety of different statistics about the system since it was last restarted. The contents of `/proc/stat`, which can be quite long, begins something like this:

```
cpu 1139111 3689 234449 84378914
cpu0 1139111 3689 234449 84378914
page 2675248 8567956
swap 10022 19226
intr 93326523 85756163 174412 0 3 3 0 6 0 1 0 428620 0 60330 0 1368304 5538681
disk_io: (3,0): (1408049,445601,5349480,962448,17135856)
ctxt 27269477
btime 886490134
processes 206458
```

Some of the more popular statistics include:

- `cpu` — Measures the number of *jiffies* (1/100 of a second) that the system has been in user mode, user mode with low priority (*nice*), system mode, and the idle task, respectively. The total for all CPUs is given at the top, and each individual CPU is listed below with its own statistics.
- `page` — The number of memory pages the system has written in and out to disk.
- `swap` — The number of swap pages the system has brought in and out.
- `intr` — The number of interrupts the system has experienced.
- `btime` — The boot time, measured in the number of seconds since January 1, 1970, otherwise known as the *epoch*.

2.2.28. `/proc/swaps`

This file measures swap space and its utilization. For a system with only one swap partition, the output of `/proc/swap` may look similar to this:

```
Filename      Type      Size      Used      Priority
/dev/hda6    partition 136512    20024    -1
```

While some of this information can be found in other files in the `/proc/` directory, `/proc/swap` provides a snapshot of every swap filename, type of swap space, the total size, and the amount of this space that is in use (in kilobytes). The priority column is useful when multiple swap files are in use. The lower the priority, the more likely the swap file is to be used.

2.2.29. `/proc/uptime`

This file contains information about how long the system has on since its last restart. The output of `/proc/uptime` is quite minimal:

```
350735.47 234388.90
```

The first number tells you the total number of seconds the system has been up. The second number tells you how much of that time the machine has spent idle in seconds.

2.2.30. `/proc/version`

This file tells you the versions of the Linux kernel and `gcc`, as well as the version of Red Hat Linux installed on the system:

```
Linux version 2.4.18-0.40 (user@foo.redhat.com) (gcc version 2.96 20000731
(Red Hat Linux 7.2 2.96-102)) #1 Tue May 28 04:28:05 EDT 2002
```

This information is used for a variety of purposes, including the version data presented when a user logs in.

2.3. Directories in `/proc/`

Common groups of information concerning the kernel are grouped into directories and subdirectories within the `/proc/` directory.

2.3.1. Process Directories

Every `/proc/` directory contains a number of directories numerical names. A listing of them may start off like this:

```
dr-xr-xr-x  3 root    root          0 Feb 13 01:28 1
dr-xr-xr-x  3 root    root          0 Feb 13 01:28 1010
dr-xr-xr-x  3 xfs     xfs           0 Feb 13 01:28 1087
dr-xr-xr-x  3 daemon  daemon       0 Feb 13 01:28 1123
dr-xr-xr-x  3 root    root          0 Feb 13 01:28 11307
dr-xr-xr-x  3 apache  apache       0 Feb 13 01:28 13660
dr-xr-xr-x  3 rpc     rpc           0 Feb 13 01:28 637
dr-xr-xr-x  3 rpcuser rpcuser      0 Feb 13 01:28 666
```

These directories are called *process directories*, as they are named after a program's process ID and contain information specific to that process. The owner and group of each process directory is set to the user running the process. When the process is terminated, its `/proc/` process directory vanishes.

Each process directory contains the following files:

- `cmdline` — This file contains the command issued when starting the process.
- `cpu` — Provides specific information about the utilization of each of the system's CPUs. A process running on a dual CPU system produces output similar to this:

```
cpu 11 3
cpu0 0 0
cpu1 11 3
```

- `cwd` — A symlink to the current working directory for the process.
- `environ` — Gives a list of the environment variables for the process. The environment variable is given in all upper-case characters, and the value is in lower-case characters.
- `exe` — A symlink to the executable of this process.
- `fd` — A directory containing all of the file descriptors for a particular process. These are given in numbered links:

```
total 0
lrwx----- 1 root    root      64 May  8 11:31 0 -> /dev/null
lrwx----- 1 root    root      64 May  8 11:31 1 -> /dev/null
lrwx----- 1 root    root      64 May  8 11:31 2 -> /dev/null
lrwx----- 1 root    root      64 May  8 11:31 3 -> /dev/ptmx
lrwx----- 1 root    root      64 May  8 11:31 4 -> socket:[7774817]
lrwx----- 1 root    root      64 May  8 11:31 5 -> /dev/ptmx
lrwx----- 1 root    root      64 May  8 11:31 6 -> socket:[7774829]
lrwx----- 1 root    root      64 May  8 11:31 7 -> /dev/ptmx
```

- `maps` — Contains memory maps to the various executables and library files associated with this process. This file can be rather long, depending upon the complexity of the process, but sample output from the `sshd` process begins like this:

```
08048000-08086000 r-xp 00000000 03:03 391479 /usr/sbin/sshd
08086000-08088000 rw-p 0003e000 03:03 391479 /usr/sbin/sshd
08088000-08095000 rwxp 00000000 00:00 0
40000000-40013000 r-xp 00000000 03:03 293205 /lib/ld-2.2.5.so
40013000-40014000 rw-p 00013000 03:03 293205 /lib/ld-2.2.5.so
40031000-40038000 r-xp 00000000 03:03 293282 /lib/libpam.so.0.75
40038000-40039000 rw-p 00006000 03:03 293282 /lib/libpam.so.0.75
40039000-4003a000 rw-p 00000000 00:00 0
4003a000-4003c000 r-xp 00000000 03:03 293218 /lib/libdl-2.2.5.so
4003c000-4003d000 rw-p 00001000 03:03 293218 /lib/libdl-2.2.5.so
```

- `mem` — The memory held by the process. This file cannot be read by the user.
- `root` — A link to the root directory of the process.
- `stat` — The status of the process.
- `statm` — The status of the memory in use by the process. Below is a sample `/proc/statm` file:
263 210 210 5 0 205 0

The seven columns relate to different memory statistics for the process. From left to right, they report the following aspects of the memory used:

1. Total program size, in kilobytes
2. Size of memory portions, in kilobytes
3. Number of pages that are shared

4. Number of pages are code
5. Number of pages of data/stack
6. Number of pages of library
7. Number of dirty pages

- `status` — The status of the process in a more readable form than `stat` or `statm`. Sample output for `sshd` looks similar to this:

```
Name: sshd
State: S (sleeping)
Tgid: 797
Pid: 797
PPid: 1
TracerPid: 0
Uid: 0 0 0 0
Gid: 0 0 0 0
FDSize: 32
Groups:
VmSize:    3072 kB
VmLck:     0 kB
VmRSS:     840 kB
VmData:    104 kB
VmStk:     12 kB
VmExe:     300 kB
VmLib:     2528 kB
SigPnd: 0000000000000000
SigBlk: 0000000000000000
SigIgn: 80000000000001000
SigCgt: 000000000014005
CapInh: 0000000000000000
CapPrm: 00000000fffffeff
CapEff: 00000000fffffeff
```

Other than the process's name and ID, the state (such as `S` (sleeping) or `R` (running) and user/group ID running the process is available, as well as much more detailed data regarding memory usage.

2.3.1.1. `/proc/self/`

The `/proc/self/` directory is a link to the currently running process. This allows a process to look at itself without having to know its process ID.

Within a shell environment, a listing of the `/proc/self/` directory produces the same contents as listing the process directory for that process.

2.3.2. `/proc/bus/`

This directory contains information specific to the various buses available on the system. So, for example, on a standard system containing ISA, PCI, and USB busses, current data on each of these buses is available in its directory under `/proc/bus/`.

The contents of the subdirectories and files available varies greatly on the precise configuration of your system. However, each of the directories for each of the bus types has at least one directory for each bus of that type. These individual bus directories, usually signified with numbers, such as `00`, contains binary files that refer to the various devices available on that bus.

So, for example, a system with a USB bus but no USB devices connected to it has a `/proc/bus/usb/` directory containing several files:

```
total 0
dr-xr-xr-x   1 root   root           0 May  3 16:25 001
-r--r--r--   1 root   root           0 May  3 16:25 devices
-r--r--r--   1 root   root           0 May  3 16:25 drivers
```

The `/proc/bus/usb/` directory contains files that track the various devices on any USB buses, as well as the drivers required to use them. The `/proc/bus/usb/001/` directory contains all devices on the first USB bus. By looking at the contents of the `devices` file, you can identify the USB root hub on the motherboard:

```
T: Bus=01 Lev=00 Prnt=00 Port=00 Cnt=00 Dev#= 1 Spd=12 MxCh= 2
B: Alloc= 0/900 us ( 0%), #Int= 0, #Iso= 0
D: Ver= 1.00 Cls=09(hub ) Sub=00 Prot=00 MxPS= 8 #Cfgs= 1
P: Vendor=0000 ProdID=0000 Rev= 0.00
S: Product=USB UHCI Root Hub
S: SerialNumber=d400
C:* #Ifs= 1 Cfg#= 1 Atr=40 MxPwr= 0mA
I: If#= 0 Alt= 0 #EPs= 1 Cls=09(hub ) Sub=00 Prot=00 Driver=hub
E: Ad=81(I) Atr=03(Int.) MxPS= 8 Iv1=255ms
```

2.3.3. `/proc/driver/`

This directory contains information for specific drivers in use by the kernel.

A common file found here is `rtc`, which provides output from the driver for the system's *Real Time Clock (RTC)*, the device that keeps the time while the system is switched off. Sample output from `/proc/driver/rtc` looks like this:

```
rtc_time : 01:38:43
rtc_date : 1998-02-13
rtc_epoch : 1900
alarm : 00:00:00
DST_enable : no
BCD : yes
24hr : yes
square_wave : no
alarm_IRQ : no
update_IRQ : no
periodic_IRQ : no
periodic_freq : 1024
batt_status : okay
```

For more information about the RTC, review `/usr/src/linux-2.4/Documentation/rtc.txt`.

2.3.4. `/proc/fs`

This directory shows which file systems are exported. If you are running an NFS server, you can type `cat /proc/fs/nfs/exports` to view the file systems being shared and the permissions granted for the those file systems. For more on sharing filesystem with NFS, see Chapter 17.

2.3.5. `/proc/ide/`

This directory holds information about IDE devices on the system. Each IDE channel is represented as a separate directory, such as `/proc/ide/ide0` and `/proc/ide/ide1`. In addition, a `drivers` file is also available, providing the version number of the various drivers used on the IDE channels:

```
ide-cdrom version 4.59
ide-floppy version 0.97
ide-disk version 1.10
```

Many chipsets also provide an informational file in this directory that gives additional data concerning the drives connected through the channels. For example, a generic Intel PIIX4 Ultra 33 chipset produces a `/proc/ide/piix` that will tell you whether DMA or UDMA is enabled for the devices on the IDE channels:

```

                                Intel PIIX4 Ultra 33 Chipset.
----- Primary Channel ----- Secondary Channel -----
                                enabled                enabled
----- drive0 ----- drive1 ----- drive0 ----- drive1 -----
DMA enabled:   yes                no                yes                no
UDMA enabled:  yes                no                no                 no
UDMA enabled:  2                  X                 X                 X
UDMA
DMA
PIO
```

Navigating into the directory for an IDE channel, such as `ide0`, provides additional information. The `channel` file provides the channel number, while the `model` tells you the bus type for the channel (such as `pci`).

2.3.5.1. The Device Directory

Within each IDE channel directory is a device directory. The name of the device directory corresponds to the drive letter in the `/dev/` directory. For instance the first IDE drive on `ide0` would be `hda`.

Note

There is a symlink to each of these device directories in the `/proc/ide/` directory.

Each device directory contains a collection of information and statistics. The contents of these directories vary according to the type of device connected. Some of the more useful files common to many devices include:

- `cache` — The device's cache.
- `capacity` — The capacity of the device, in 512 byte blocks.
- `driver` — The driver and version used to control the device.
- `geometry` — The physical and logical geometry of the device.
- `media` — The type of device, such as a disk.

- `model` — The model name or number of the device.
- `settings` — A collection of current parameters of the device. This file usually contains quite a bit of useful, technical information. A sample `settings` file for a standard IDE hard disk looks similar to this:

name	value	min	max	mode
----	-----	---	---	----
<code>bios_cyl</code>	784	0	65535	<code>rw</code>
<code>bios_head</code>	255	0	255	<code>rw</code>
<code>bios_sect</code>	63	0	63	<code>rw</code>
<code>breada_readahead</code>	4	0	127	<code>rw</code>
<code>bswap</code>	0	0	1	<code>r</code>
<code>current_speed</code>	66	0	69	<code>rw</code>
<code>file_readahead</code>	0	0	2097151	<code>rw</code>
<code>ide_scsi</code>	0	0	1	<code>rw</code>
<code>init_speed</code>	66	0	69	<code>rw</code>
<code>io_32bit</code>	0	0	3	<code>rw</code>
<code>keepsettings</code>	0	0	1	<code>rw</code>
<code>lun</code>	0	0	7	<code>rw</code>
<code>max_kb_per_request</code>	64	1	127	<code>rw</code>
<code>multcount</code>	8	0	8	<code>rw</code>
<code>nicel</code>	1	0	1	<code>rw</code>
<code>nowerr</code>	0	0	1	<code>rw</code>
<code>number</code>	0	0	3	<code>rw</code>
<code>pio_mode</code>	<code>write-only</code>	0	255	<code>w</code>
<code>slow</code>	0	0	1	<code>rw</code>
<code>unmaskirq</code>	0	0	1	<code>rw</code>
<code>using_dma</code>	1	0	1	<code>rw</code>

2.3.6. `/proc/irq/`

This directory is used to set IRQ to CPU affinity, which allows you to connect a particular IRQ to only one CPU. Alternatively, you can exclude a CPU from handling any IRQs.

Each IRQ has its own directory, allowing for individual configuration of each IRQ. The `/proc/irq/proc_cpu_mask` file is a bitmask that contains the default values for the `smp_affinity` file in the IRQ directory. The values in `smp_affinity` specify which CPUs handle that particular IRQ.

`/usr/src/linux-2.4/Documentation/filesystems/proc.txt` contains more information.

2.3.7. `/proc/net/`

This directory provides a comprehensive look at various networking parameters and statistics. Each of the files covers a specific range of information related to networking on the system. Below is a partial listing of these virtual files:

- `arp` — Contains the kernel's ARP table. This file is particularly useful for connecting hardware address to an IP address on a system.
- `atm` — A directory containing files with various *Asynchronous Transfer Mode (ATM)* settings and statistics. This directory is primarily used with ATM networking and ADSL cards.
- `dev` — Lists the various network devices configured on the system, complete with transmit and receive statistics. This file will quickly tell you the number of bytes each interface has sent and received, the number of packets inbound and outbound, the number of errors seen, the number of packets dropped, and more.

- `dev_mcast` — Displays the various Layer2 multicast groups each device is listening to.
- `igmp` — Lists the IP multicast addresses which this system joined.
- `ip_fwchains` — If `ipchains` are in use, this virtual file reveals any current rule.
- `ip_fwnames` — If `ipchains` are in use, this virtual file lists all firewall chain names.
- `ip_masquerade` — Provides a table of masquerading information under `ipchains`.
- `ip_mr_cache` — List of the multicast routing cache.
- `ip_mr_vif` — List of multicast virtual interfaces.
- `netstat` — Contains a broad yet detailed collection of networking statistics, including TCP timeouts, SYN cookies sent and received, and much more.
- `psched` — List of global packet scheduler parameters.
- `raw` — List of raw device statistics.
- `route` — Displays the kernel's routing table.
- `rt_cache` — Contains the current routing cache.
- `snmp` — List of Simple Network Management Protocol (SNMP) data for various networking protocols in use.
- `sockstat` — Provides socket statistics.
- `tcp` — Contains detailed TCP socket information.
- `tr_rif` — The token ring RIF routing table.
- `udp` — Contains detailed UDP socket information.
- `unix` — Lists UNIX domain sockets currently in use.
- `wireless` — Lists wireless interface data.

2.3.8. `/proc/scsi/`

This directory is analogous to the `/proc/ide/` directory only it is for connected SCSI devices.

The primary file in this directory is `/proc/scsi/scsi`, which contains a list of every recognized SCSI device. From this listing, the type of devices, as well as the model name, vendor, SCSI channel and ID data is available.

For example, if a system contains a SCSI CD-ROM, tape drive, hard drives, and RAID controller, this file would look similar to this:

```
Attached devices:
Host: scsi1 Channel: 00 Id: 05 Lun: 00
  Vendor: NEC      Model: CD-ROM DRIVE:466 Rev: 1.06
  Type:   CD-ROM   ANSI SCSI revision: 02
Host: scsi1 Channel: 00 Id: 06 Lun: 00
  Vendor: ARCHIVE  Model: Python 04106-XXX Rev: 7350
  Type:   Sequential-Access ANSI SCSI revision: 02
Host: scsi2 Channel: 00 Id: 06 Lun: 00
  Vendor: DELL    Model: 1x6 U2W SCSI BP  Rev: 5.35
  Type:   Processor ANSI SCSI revision: 02
Host: scsi2 Channel: 02 Id: 00 Lun: 00
  Vendor: MegaRAID Model: LD0 RAID5 34556R Rev: 1.01
  Type:   Direct-Access ANSI SCSI revision: 02
```

Each SCSI driver used by the system has its own directory in `/proc/scsi/`, which contains files specific to each SCSI controller using that driver. So, for the example system above, `aic7xxx` and

megaraid directories are present, as those two drivers are being utilized. The files in each of the directories typically contain IO address range, IRQ, and statistics for the particular SCSI controller using that driver. Each controller can report a different type and amount of information. The Adaptec AIC-7880 Ultra SCSI host adapter's file in this example system produces the following output:

```
Adaptec AIC7xxx driver version: 5.1.20/3.2.4
Compile Options:
  TCQ Enabled By Default : Disabled
  AIC7XXX_PROC_STATS     : Enabled
  AIC7XXX_RESET_DELAY    : 5

Adapter Configuration:
  SCSI Adapter: Adaptec AIC-7880 Ultra SCSI host adapter
                Ultra Narrow Controller
  PCI MMAPed I/O Base: 0xfcffe000
  Adapter SEEPROM Config: SEEPROM found and used.
  Adaptec SCSI BIOS: Enabled
                    IRQ: 30
                    SCBs: Active 0, Max Active 1,
                          Allocated 15, HW 16, Page 255
                    Interrupts: 33726
                    BIOS Control Word: 0x18a6
                    Adapter Control Word: 0x1c5f
                    Extended Translation: Enabled
  Disconnect Enable Flags: 0x00ff
                    Ultra Enable Flags: 0x0020
  Tag Queue Enable Flags: 0x0000
  Ordered Queue Tag Flags: 0x0000
  Default Tag Queue Depth: 8
                    Tagged Queue By Device array for aic7xxx host instance 1:
                    {255,255,255,255,255,255,255,255,255,255,255,255,255,255,255}
                    Actual queue depth per device for aic7xxx host instance 1:
                    {1,1,1,1,1,1,1,1,1,1,1,1,1,1,1}
```

Statistics:

```
(scsil:0:5:0)
Device using Narrow/Sync transfers at 20.0 MByte/sec, offset 15
Transinfo settings: current(12/15/0/0), goal(12/15/0/0), user(12/15/0/0)
Total transfers 0 (0 reads and 0 writes)
  < 2K   2K+   4K+   8K+   16K+   32K+   64K+   128K+
Reads:   0     0     0     0     0     0     0     0
Writes:  0     0     0     0     0     0     0     0
```

```
(scsil:0:6:0)
Device using Narrow/Sync transfers at 10.0 MByte/sec, offset 15
Transinfo settings: current(25/15/0/0), goal(12/15/0/0), user(12/15/0/0)
Total transfers 132 (0 reads and 132 writes)
  < 2K   2K+   4K+   8K+   16K+   32K+   64K+   128K+
Reads:   0     0     0     0     0     0     0     0
Writes:  0     0     0     1    131    0     0     0
```

From this screen, you can see the transfer speed to the various SCSI devices connected to the controller based on channel ID, as well as detailed statistics concerning the amount and sizes of files read or written by that device. For instance, from the output above you can see in the can see that this

controller is communicating with the CD-ROM at 20 megabytes per second, while the tape drive is only connected at 10 megabytes per second.

2.3.9. `/proc/sys/`

The `/proc/sys/` directory is different from others in `/proc/` because it not only provides information about the system but also allows you to make configuration changes to the kernel. This allows the administrator of the machine to immediately enable and disable kernel features.

Warning

Use caution when changing settings on a production system using the various files in the `/proc/sys/` directory. Changing the wrong setting may render the kernel unstable, requiring a reboot of the system.

For this reason, be sure you know the valid options for that file and the expected outcome before attempting to change a value in `/proc/sys/`.

A good way to determine if a particular file can be configured or is only designed to provide information is to list it with the `-l` flag in the terminal. If the file is writable, you may use it to configure the kernel. For example, a partial listing of `/proc/sys/fs` looks like this:

```
-r--r--r-- 1 root root 0 May 10 16:14 dentry-state
-rw-r--r-- 1 root root 0 May 10 16:14 dir-notify-enable
-r--r--r-- 1 root root 0 May 10 16:14 dquot-nr
-rw-r--r-- 1 root root 0 May 10 16:14 file-max
-r--r--r-- 1 root root 0 May 10 16:14 file-nr
```

In this listing, the files `dir-notify-enable` and `file-max` can be written to and, therefore, can be used to configure the kernel. The other files only provide feedback on current settings.

Changing a value within a `/proc/sys/` file is done by echoing the new value into the file. For example, to enable the System Request Key on a running kernel, type the command:

```
echo 1 > /proc/sys/kernel/sysrq
```

This will change the `sysrq` file's value from 0 (off) to 1 (on).

The purpose of the System Request Key is to allow you to immediately instruct the kernel to do a number of important activities by using a simple key combination, such as immediately shutting down or restarting a system, syncing all mounted file systems, or dumping important information to your console. This feature is most useful when using a development kernel or if you are experiencing system freezes. However, it is considered a security risk for an unattended console and is therefore turned off by default under Red Hat Linux.

Refer to `/usr/src/linux-2.4/Documentation/sysrq.txt` for more information on the System Request Key.

A few `/proc/sys/` configuration files contain more than one value. In order to correctly send new values to them, place a space character between each value passed with the `echo` command, such as is done in this example:

```
echo 4 2 45 > /proc/sys/kernel/acct
```

**Note**

Any configuration changes you make using the `echo` command will disappear when the system is restarted. To make your configuration changes take effect at the time the system is booted, see Section 2.4.

The `/proc/sys/` directory contains several subdirectories controlling different aspects of a running kernel.

2.3.9.1. `/proc/sys/dev/`

This directory provides parameters for particular devices on the system. Most systems have at least two directories, `cdrom` and `raid`, but customized kernels can have others, such as `parport`, which provides the ability to share one parallel port between multiple device drivers.

The `cdrom` directory contains a file called `info`, which reveals a number of important CD-ROM parameters:

```
CD-ROM information, Id: cdrom.c 3.12 2000/10/18
```

```
drive name: hdc
drive speed: 32
drive # of slots: 1
Can close tray: 1
Can open tray: 1
Can lock tray: 1
Can change speed: 1
Can select disk: 0
Can read multisession: 1
Can read MCN: 1
Reports media changed: 1
Can play audio: 1
Can write CD-R: 0
Can write CD-RW: 0
Can read DVD: 0
Can write DVD-R: 0
Can write DVD-RAM: 0
```

This file can be quickly scanned to discover the qualities of an unknown CD-ROM, at least in the eyes of the kernel. If multiple CD-ROMs are available on a system, each device is given its own column of information.

Various files in `/proc/sys/dev/cdrom`, such as `autoclose` and `checkmedia`, can be used to control the system's CD-ROM. Use the `echo` command to enable or disable to disable these features.

If RAID support is compiled into the kernel, a `/proc/sys/dev/raid/` directory will be available with at least two files in it: `speed_limit_min` and `speed_limit_max`. These settings determine how much to accelerate the RAID device for particularly I/O intensive tasks, such as resyncing the disks.

2.3.9.2. `/proc/sys/fs/`

This directory contains an array of options and information concerning various aspects of the file system, including quota, file handle, inode, and dentry information.

The `binfmt_misc` directory is used to provide kernel support for miscellaneous binary formats.

The important files in `/proc/sys/fs` include:

- `dentry-state` — Provides the status of the directory cache. The file looks similar to this:
57411 52939 45 0 0 0

The first number reveals the total number of directory cache entries, while the second number displays the number of unused entries. The third number tells the number of seconds between when a directory has been freed and when it can be reclaimed, and the fourth measures the pages currently requested by the system. The last two numbers are not used and currently display only zeros.

- `dquot-nr` — Shows the maximum number of cached disk quota entries.
- `file-max` — Allows you to change the maximum number of file handles that the kernel will allocate. Raising the value in this file can resolve errors caused by a lack of available file handles.
- `file-nr` — Displays the number of allocated file handles, used file handles, and the maximum number of file handles.
- `overflowgid` and `overflowuid` — Defines the fixed group ID and user ID, respectively, for use with file systems that only support 16-bit group and user IDs.
- `super-max` — Controls the maximum number of superblocks available.
- `super-nr` — Displays the current number of superblocks in use.

2.3.9.3. `/proc/sys/kernel/`

This directory contains a variety of different configuration files that directly affect the operation of the kernel. Some of the most important files include:

- `acct` — Controls the suspension of process accounting based on the percentage of free space available on the file system containing the log. By default, the file looks like this:
4 2 30

The second value sets the threshold percentage of free space when logging will be suspended, while the first value dictates the percentage of free space required for logging to resume. The third value sets the interval in seconds that the kernel polls the file system to see if logging should be suspended or resumed.

- `cap-bound` — Controls the *capability bounding* settings, which provide a list of capabilities for any process on the system. If a capability is not listed here, then no process, no matter how privileged, can do it. The idea is to make the system more secure by ensuring that certain things cannot happen, at least beyond a certain point in the boot process.

The various values that are possible here are beyond the scope of this manual, so consult the kernel documentation for more information.

- `ctrl-alt-del` — Controls whether [Ctrl]-[Alt]-[Delete] will gracefully restart the computer using `init` (value 0) or force an immediate reboot without syncing the dirty buffers to disk (value 1).
- `domainname` — Allows you to configure the system's domain name, such as `subgenius.com`.
- `hostname` — Allows you to configure the system's host name, such as `bob.subgenius.com`.
- `hotplug` — Configures the utility to be used when a configuration change is detected by the system. This is primarily used with USB and Cardbus PCI. The default value of `/sbin/hotplug` should not be changed unless you are testing a new program to fulfill this role.
- `modprobe` — Sets the location of the program to be used to load kernel modules when necessary. The default value of `/sbin/modprobe` signifies that `kmod` will call it to actually load the module when a kernel thread calls `kmod`.
- `msgmax` — Sets the maximum size of any message sent from one process to another is set to 8192 bytes by default. You should be careful about raising this value, as queued messages between

processes are stored in non-swappable kernel memory. Any increase in `msgmax` would increase RAM requirements for the system.

- `msgmnb` — Sets the maximum number of bytes in a single message queue. The default is 16384.
- `msgmni` — Sets the maximum number of message queue identifiers. The default is 16.
- `osrelease` — Lists the Linux kernel release number. This file can only be altered by changing the kernel source and recompiling.
- `ostype` — Displays the type of operating system. By default, this file is set to `Linux`, and this value can only be changed by changing the kernel source and recompiling.
- `overflowgid` and `overflowuid` — Defines the fixed group ID and user ID, respectively, for use with system calls on architectures that only support 16-bit group and user IDs.
- `panic` — Defines the number of seconds the kernel will postpone rebooting when the system experiences a kernel panic. By default, the value is set to 0, which disables automatic rebooting after a panic.
- `printk` — This file controls a variety of settings related to printing or logging error messages. Each error message reported by the kernel has a *loglevel* associated with it that defines the importance of the message. The *loglevel* values break down in this order:
 - 0 — Kernel emergency. The system is unusable.
 - 1 — Kernel alert. Action must be taken immediately.
 - 2 — Condition of the kernel is considered critical.
 - 3 — General kernel error condition.
 - 4 — General kernel warning condition.
 - 5 — Kernel notice of a normal but significant condition.
 - 6 — Kernel informational message.
 - 7 — Kernel debug-level messages.

Four values are found in the `printk` file:

```
6 4 1 7
```

Each of these values defines a different rule for dealing with error messages. The first value, called the *console loglevel*, defines the lowest priority of messages that will be printed to the console. (Note that, the lower the priority, the higher the *loglevel* number.) The second value sets the default *loglevel* for messages without an explicit *loglevel* attached to them. The third value sets the lowest possible *loglevel* configuration for the console *loglevel*. The last value sets the default value for the console *loglevel*.

- `rtsig-max` — Configures the maximum number of POSIX realtime signals that the system may have queued at any one time. The default value is 1024.
- `rtsig-nr` — The current number of POSIX realtime signals queued by the kernel.
- `sem` — This file configures semaphore settings within the kernel. A *semaphore* is a System V IPC object that is used to control utilization of a particular process.
- `shmall` — Sets the total amount of shared memory that can be used at one time on the system, in bytes. By default, this value is 2097152.
- `shmmax` — Sets the largest shared memory segment size allowed by the kernel, in bytes. By default, this value is 33554432. However, the kernel supports much larger values than this.
- `shmni` — Sets the maximum number of shared memory segments for the whole system. By default, this value is 4096.
- `sysrq` — Activates the System Request Key, if this value is set to anything other than the default of 0. See Section 2.3.9 for details about the System Request Key.

- `threads-max` — Sets the maximum number of threads to be used by the kernel, with a default value of 2048.
- `version` — Displays the date and time the kernel was last compiled. The first field in this file, such as #3, relates to the number of times a kernel was built from the source base.

The `random` directory stores a number of values related to generating random numbers for the kernel.

2.3.9.4. `/proc/sys/net/`

This directory contains assorted directories concerning various networking topics. Various configurations at the time of kernel compilation make available different directories here, such as `appletalk`, `ethernet`, `ipv4`, `ipx`, and `ipv6`. Within these directories, you can adjust the assorted networking values for that configuration on a running system.

Given the wide variety of possible networking options available with Linux and the great amount of space required to discuss them, only the most common `/proc/sys/net/` directories will be discussed.

The `core` directory contains a variety of settings that control the interaction between the kernel and networking layers. The most important files there are:

- `message_burst` — The amount of time in tenths of a second required to write a new warning message. This is used to prevent *Denial of Service (DoS)* attacks. The default setting is 50.
- `message_cost` — Also used to prevent DoS attacks by placing a cost on every warning message. The higher the value of this file (default of 5), the more likely the warning message will be ignored.

The idea of a DoS attack is to bombard your system with requests that generate errors and fill up disk partitions with log files or require all of your system's resources to handle the error logging. The settings in `message_burst` and `message_cost` are designed to be modified based on your system's acceptable risk versus the need for comprehensive logging.

- `netdev_max_backlog` — Sets the maximum number of packets allowed to queue when a particular interface receives packets faster than the kernel can process them. The default value for this file is 300.
- `optmem_max` — Configures the maximum ancillary buffer size allowed per socket.
- `rmem_default` — Sets the receive socket buffer's default size in bytes.
- `rmem_max` — Sets the receive socket buffer's maximum size in bytes.
- `wmem_default` — Sets the send socket buffer's default size in bytes.
- `wmem_max` — Sets the send socket buffer's maximum size in bytes.

The `ipv4` directory contains additional networking settings. Many of these settings, used in conjunction with one another, are very useful in preventing attacks on the system or using the system to act as a router.

Caution

An erroneous change to these files may affect your remote connectivity to the system.

Here are some of the most important files in the `/proc/sys/net/ipv4/` directory:

- `icmp_destunreach_rate`, `icmp_echoreply_rate`, `icmp_paramprob_rate` and `icmp_timeexceed_rate` — Set the maximum ICMP send packet rate, in hundredths of a second, to hosts under certain conditions. A setting of 0 removes any delay and is not a good idea.

- `icmp_echo_ignore_all` and `icmp_echo_ignore_broadcasts` — Allows the kernel to ignore ICMP ECHO packets from every host or only those originating from broadcast and multicast addresses, respectively. A value of 0 allows the kernel to respond, while a value of 1 ignores the packets.
- `ip_default_ttl` — Sets the default *Time To Live (TTL)*, which limits the number of hops a packet may make before reaching its destination. Increasing this value can diminish system performance.
- `ip_forward` — Permits interfaces on the system to forward packets to one other. By default, this file is set to 0. Setting this file to 1 will enable network packet forwarding.
- `ip_local_port_range` — Specifies the range of ports to be used by TCP or UDP when a local port is needed. The first number is the lowest port to be used, and the second number specifies the highest port. Any systems that expect to require more ports than the default 1024 to 4999 should use the 32768 to 61000 range in this file.
- `tcp_syn_retries` — Provides a limit on the number of times your system will re-transmit a SYN packet when attempting to make a connection.
- `tcp_retries1` — Sets the number of permitted re-transmissions attempting to answer an incoming connection. Default of 3.
- `tcp_retries2` — Sets the number of permitted re-transmissions of TCP packets. Default of 15.

The `/usr/src/linux-2.4/Documentation/networking/ip-sysctl.txt` file contains a complete list of files and options available in the `/proc/sys/net/ipv4/` directory.

A number of other directories exist within the `/proc/sys/net/ipv4/` directory cover specific topics. The `conf` directory allows each of the systems interfaces to be configured in different ways, including the use of a default settings for unconfigured devices (in the `default` subdirectory) and settings that override all special configurations (in the `all` subdirectory).

In order to control connections between direct neighbors, meaning any other system directly connected to your system, the `neigh` directory allows special configurations for each interface. This would allow you to treat systems differently that you trust more due to their relatively proximity to your system. At the same time, it also makes it easy to put strict rules in place for systems several hops away.

Routing over IPV4 also has its own directory, `route`. Unlike `conf` and `neigh`, the `route` directory contains specifications that apply to routing with any interfaces on the system. Many of these settings, such as `max_size`, `max_delay`, and `min_delay`, relate to controlling the size of the routing cache. To clear the routing cache, simply write any value to the `flush` file.

Additional information about these directories and the possible values for their configuration files can be found in `/usr/src/linux-2.4/Documentation/filesystems/proc.txt`.

2.3.9.5. `/proc/sys/vm/`

This directory facilitates the configuration of the Linux kernel's virtual memory (VM) subsystem. The kernel makes extensive and intelligent use of virtual memory, which is commonly called swap space.

The following files are commonly found in the `/proc/sys/vm/` directory:

- `bdflush` — Sets various values related to the `bdflush` kernel daemon.
- `buffermem` — Allows you to control the percentage amount of total system memory to be used for buffer memory. Typical output for this file looks like this:

```
2      10      60
```

The first and last values set the minimum and maximum percentage of memory to be used as buffer memory, respectively. The middle value sets the percentage of system memory dedicated to buffer memory where the memory management subsystem will begin to clear buffer cache more than other kinds of memory to compensate for a general lack of free memory.

- `kswapd` — Sets various values concerned with the kernel swap-out daemon, `kswapd`. This file has three values:

```
512 32 8
```

The first value sets the maximum number of pages that `kswapd` will attempt to free in a single attempt. The larger this number, the more aggressively the kernel can move to free pages. The second value sets the minimum number of times that `kswapd` attempts to free a page. The third value sets the number of pages `kswapd` attempts to write in a single attempt. Proper tuning of this final value can improve performance on a system using a lot of swap space by telling the kernel to write pages in large chunks, minimizing the number of disk seeks.

- `max_map_count` — Configures the maximum number of memory map areas a process may have. In most cases, the default value of 65536 is appropriate.
- `overcommit_memory` — When set to the default value of 0 the kernel estimates the amount of memory available and fails requests that are blatantly invalid. Unfortunately, since memory is allocated using a heuristic rather than a precise algorithm, it can sometimes overload the system.

If `overcommit_memory` is set to 1, then the potential for system overload is increased, but so is the performance for memory intensive tasks, such as those used by some scientific software.

For customers who need more less risk of over memory commitment, the following two option have been added. Setting `overcommit_memory` to 2 fails a memory request adds up to more than half of the physical RAM, plus swap. Setting it to 3 fails if a memory request adds up to more than swap alone can hold.

- `pagecache` — Controls the amount of memory used by the page cache. The values in `pagecache` are percentages, and they work in a similar way as `buffermem` to enforce minimums and maximums of available page cache memory.
- `page-cluster` — Sets the number of pages read in a single attempt. The default value of 4, which actually relates to 16 pages, is appropriate for most systems.
- `pagetable_cache` — Controls the number of page tables that are cached on a per-processor basis. The first and second values relate to the minimum and maximum number of page tables to set aside, respectively.

The `/usr/src/linux-2.4/Documentation/sysctl/vm.txt` file contains additional information on these various files.

2.3.10. `/proc/sysvipc/`

This directory contain information about System V IPC resources. The files in this directory relate to System V IPC calls for messages (`msg`), semaphores (`sem`), and shared memory (`shm`).

2.3.11. `/proc/tty/`

This directory contains information about the available and currently used tty devices on the system. Originally called a *teletype device*, any character-based data terminals are called *tty devices*.

In Linux, there are three different kinds of tty devices. *Serial devices* are used with serial connections, such as over a modem or using a serial cable. *Virtual terminals* create the common console connection, such as the virtual consoles available when pressing [Alt]-[<F-key>] at the system console. *Pseudo terminals* create a two-way communication that is used by some higher level applications, such as **X11**. The `drivers` file is a list of the current tty devices in use:

```
serial          /dev/cua        5  64-127 serial:callout
serial          /dev/ttyS       4  64-127 serial
pty_slave       /dev/pts        136 0-255 pty:slave
```

<code>pty_master</code>	<code>/dev/ptm</code>	128	0-255	<code>pty:master</code>
<code>pty_slave</code>	<code>/dev/ttyp</code>	3	0-255	<code>pty:slave</code>
<code>pty_master</code>	<code>/dev/pty</code>	2	0-255	<code>pty:master</code>
<code>/dev/vc/0</code>	<code>/dev/vc/0</code>	4	0	<code>system:vtmaster</code>
<code>/dev/ptmx</code>	<code>/dev/ptmx</code>	5	2	<code>system</code>
<code>/dev/console</code>	<code>/dev/console</code>	5	1	<code>system:console</code>
<code>/dev/tty</code>	<code>/dev/tty</code>	5	0	<code>system:/dev/tty</code>
<code>unknown</code>	<code>/dev/vc/%d</code>	4	1-63	<code>console</code>

The `/proc/tty/driver/serial` file lists the usage statistics and status of each of the serial tty lines.

In order that tty devices can be used in a similar way as network devices, the Linux kernel will enforce *line discipline* on the device. This allows the driver to place a specific type of header with every block of data transmitted over the device, making it possible for the remote end of the connection to be able to see that block of data as just one in a stream of data blocks. SLIP and PPP are common line disciplines, and each are commonly used to connect systems to one other over a serial link.

Registered line disciplines are stored in the `ldiscs` file, with detailed information available in the `ldisc` directory.

2.4. Using `sysctl`

The `sysctl` command is used to view, set, and automate kernel settings in the `/proc/sys/` directory.

To get a quick overview of all settings configurable in the `/proc/sys/` directory, type the `sysctl -a` command as root. This will create a large, comprehensive list, a small portion of which looks something like this:

```
net.ipv4.route.min_delay = 2
kernel.sysrq = 0
kernel.sem = 250      32000      32      128
```

This is the same basic information you would see if you viewed each of the files individually. The only difference is the file location. The `/proc/sys/net/ipv4/route/min_delay` file is signified by `net.ipv4.route.min_delay`, with the directory slashes replaced by dots and the `proc.sys` portion assumed.

The `sysctl` command can be use in place of `echo` to assign values to writable files in the `/proc/sys/` directory. For instance instead of using this command:

```
echo 1 > /proc/sys/kernel/sysrq
```

You can use this `sysctl` command:

```
sysctl -w kernel.sysrq="1"
kernel.sysrq = 1
```

While quickly setting single values like this in `/proc/sys/` is helpful during testing, it does not work as well on a production system, as all `/proc/sys/` special settings are lost when the machine is rebooted. To preserve the settings that you like to make permanently to your kernel, add them to the `/etc/sysctl.conf` file.

Every time the system boots, the `init` program runs the `/etc/rc.d/rc.sysinit` script. This script contains a command to execute `sysctl` using `/etc/sysctl.conf` to dictate the values passed to the kernel. Any values added to `/etc/sysctl.conf` will take effect each time the system boots.

2.5. Additional Resources

Below are additional sources of information about `/proc/`.

2.5.1. Installed Documentation

Most of the best `/proc/` documentation is available on your system.

- `/usr/src/linux-2.4/Documentation/filesystems/proc.txt` — Contains assorted, but limited, information about all aspects of the `/proc/` directory.
- `/usr/src/linux-2.4/Documentation/sysrq.txt` — An overview of System Request Key options.
- `/usr/src/linux-2.4/Documentation/sysctl` — A directory containing a variety of `sysctl` tips, including modifying values that concern the kernel (`kernel.txt`), accessing file systems (`fs.txt`), and virtual memory use (`vm.txt`).
- `/usr/src/linux-2.4/Documentation/networking/ip-sysctl.txt` — A look at various IP networking options.
- `/usr/src/linux-2.4` — Some of the most authoritative information on `/proc/` can be found by reading the kernel source code. Make sure the `kernel-source` RPM is installed on your system and look in the `/usr/src/linux-2.4` directory for the source code.

2.5.2. Useful Websites

- <http://www.linuxhq.com> — This site maintain a complete database of source, patches, and documentation for various versions of the Linux kernel.

Boot Process, Init, and Shutdown

An important and powerful aspect of Red Hat Linux is the open method it uses for starting and stopping the operating system. During boot time, Red Hat Linux loads programs in a specific and configurable order. Once booted, you are free to change the configuration files controlling the boot process as well as the configuration files for the programs started at boot-time. Similarly, system shutdown gracefully terminates processes in an organized and configurable way, although customization of this process is rarely required.

Understanding how the boot and shutdown processes work will not only allow you to easily customize Red Hat Linux to your needs, but will also make it easier to troubleshoot problems related to starting or shutting down your system.

3.1. The Boot Process

Below are the basic stages of the boot process for an x86 system:

1. The system BIOS checks the system and launches the first stage boot loader on the MBR of the primary hard disk.
2. The first stage boot loader loads itself into memory and launches the second stage boot loader from the `/boot/` partition.
3. The kernel is loaded into memory, which in turn loads any necessary modules and mounts the root partition read-only.
4. The kernel hands control of the boot process to the `/sbin/init` program.
5. The `/sbin/init` program loads all services and user-space tools, and mounts all partitions listed in `/etc/fstab`.
6. The user is presented with a login prompt for the freshly booted Linux system.

Because configuration of the boot process is more common than the customization of the shutdown process, the remainder of this chapter will discuss in detail how the boot process works and how it can be customized to suite your needs.

3.2. A Detailed Look at the Boot Process

The very beginning of the boot process varies depending the platform on which you are booting Red Hat Linux. However, once the kernel is found and loaded by the system, the default boot process is identical across all architectures. In the example outlined below, the system will be an x86 computer.

3.2.1. The BIOS

When an x86 computer is booted, the processor looks at the end of system memory for the *Basic Input/Output System* or *BIOS* program and runs it. The BIOS controls not only the first step of the boot process, but also provides the lowest level interface to peripheral devices. For this reason it is written into read-only, permanent memory and is always available for use.

Other platforms use different programs to perform low-level tasks roughly equivalent to those of the BIOS on an x86 system. For instance, Itanium-based computers use the *Extensible Firmware Interface (EFI) Shell*, while Alpha systems use the *SRM console*.

Once loaded, the BIOS tests the system, looks for and checks peripherals and then locates a valid device with which to boot the system. Usually, it first checks any floppy drives and CD-ROM drives present for bootable media, then it looks to the system's hard drives. The order of the drives searched for booting can often be controlled with a setting in BIOS. Often, the first hard drive set to boot is the C drive or the master IDE device on the primary IDE bus. The BIOS loads whatever program is residing in the first sector of this device, called the *Master Boot Record* or *MBR*, into memory. The MBR is only 512 bytes in size and contains machine code instructions for booting the machine along with the partition table. Once found and loaded the BIOS passes control whatever program is on the MBR.

3.2.2. The Boot Loader

This section looks at the boot process for the x86 platform. Depending on your system's architecture, the boot process may differ slightly. Please see Section 3.4 for a brief overview of non-x86 boot processes.

Linux boot loaders for the x86 platform are broken into at least two stages. The first stage is a small machine code binary on the MBR. Its sole job is to locate the second stage boot loader and load the first part of it into memory. Under Red Hat Linux you can install one of two boot loaders: *GRUB* or *LILO*. GRUB is the default boot loader, but LILO is available for those who require it for their hardware setup or who prefer it. For more information about configuring and using GRUB or LILO, see Chapter 4.

If you are using LILO under Red Hat Linux, the second stage boot loader uses information on the MBR to determine what boot options are available to the user. This means that any time a configuration change is made or you upgrade your kernel manually, you must run the `/sbin/lilo -v -v` command to write the appropriate information to the MBR. For details on doing this, see Section 4.8.

GRUB, on the other hand, can read ext2 partitions and therefore simply loads its configuration file — `/boot/grub/grub.conf` — when the second stage loader is called. See Section 4.7 for information on how to edit this file.

Tip

If you upgrade the kernel using the **Red Hat Update Agent**, the MBR or the `/boot/grub/grub.conf` will be updated automatically. For more information on RHN, refer to the following URL, <https://rhn.redhat.com>

Once the second stage boot loader is in memory, it presents the user with the Red Hat Linux initial, graphical screen showing the different operating systems or kernels it has been configured to boot. If you have only Red Hat Linux installed and have not changed anything in the `/etc/lilo.conf` or `/boot/grub/grub.conf`, you will only see one option for booting.

If you have configured the boot loader to boot other operating systems, this screen gives you the opportunity to select it. Use the arrow keys to highlight the operating system and press [Enter]. If you do nothing, the boot loader will load the default selection.

Note

If you installed Symmetric Multi-Processor (SMP) kernel support, you will see more than one option the first time you boot your system. Under LILO you will see `linux` and `linux-up`. Under GRUB you will see `Red Hat Linux (kernel version)` and `Red Hat Linux (kernel version-smp)`. The `linux` or `Red Hat Linux (kernel version-smp)` option is the SMP kernel. If you experience any problems with the SMP kernel, select the `linux-up` or non-SMP kernel upon rebooting.

If you need to alter the command line arguments to the kernel, see Chapter 4. For information on changing the runlevel at the GRUB or LILO prompt, see Section 3.5.

Once the second stage boot loader has determined which kernel to boot, it locates the corresponding kernel binary in the `/boot/` directory. The proper binary is the `/boot/vmlinuz-2.4.x-xx` file that corresponds to the boot loader's settings. Next the boot loader places the appropriate *initial RAM disk* image, called an *initrd*, into memory. The *initrd* is used by the kernel to load any drivers not compiled into it that are necessary to boot the system. This is particularly important if you have SCSI hard drives or are using the ext3 file system¹.

Warning

Do not remove the `/initrd/` directory from the file system for any reason. Removing this directory will cause your system to fail with a kernel panic error message at boot time.

Once the kernel and the *initrd* image are loaded into memory, the boot loader hands control of the boot process to the kernel.

3.2.3. The Kernel

When the kernel loads, it immediately initializes and configures the computer's memory. Next it configures the various hardware attached to the system, including all processors and I/O subsystems, as well as any storage devices. It then looks for the compressed *initrd* image in a predetermined location in memory, decompresses it, mounts it, and loads all necessary drivers. Next it initializes file system-related virtual devices, such as LVM or software RAID before unmounting the *initrd* disk image and freeing up all the memory it once occupied.

After the kernel has initialized all the devices on the system, it creates a root device, mounts the root partition read-only, and frees unused memory.

At this point, with the kernel loaded into memory and operational. However, with no user applications to give the user the ability to provide meaningful input to the system, not much can be done with it.

To set up the user environment, the kernel starts the `/sbin/init` command.

3.2.4. The `/sbin/init` Program

The *init* program coordinates the rest of the boot process and configures the environment for the user.

When the *init* command starts, it becomes the parent or grandparent of all of the processes that start up automatically on a Red Hat Linux system. First, it runs the `/etc/rc.d/rc.sysinit` script, which sets your environment path, starts swap, checks the file systems, and so on. Basically, `rc.sysinit` takes care of everything that your system needs to have done at system initialization. For example, most systems use a clock, so on them `rc.sysinit` reads the `/etc/sysconfig/clock` configuration file to initialize the clock. Another example is if you have special serial port processes which must be initialized, `rc.sysinit` will execute the `/etc/rc.serial` file.

The *init* command then runs the `/etc/inittab` script, which describes how the system should be set up in each SysV *init runlevel*². Among other things, the `/etc/inittab` sets the default runlevel and dictates that `/sbin/update` should be run whenever it starts a given runlevel³.

1. For details on making an *initrd*, see the section about converting to an ext3 file system in the *Official Red Hat Linux Customization Guide*.

2. For more information on SysV *init*, see Section 3.5. For more about *init* runlevels, see Section 3.6.

3. The `update` command is used to flush dirty buffers back to disk.

Next, the `init` command sets the source function library, `/etc/rc.d/init.d/functions`, for the system. This spells out how to start or kill a program and how to determine the PID of a program.

The `init` program starts all of the background processes by looking in the appropriate `rc` directory for the runlevel specified as default in `/etc/inittab`. The `rc` directories are numbered to correspond to the runlevel they represent. For instance, `/etc/rc.d/rc5.d/` is the directory for runlevel five.

When booting to runlevel 5, the `init` program looks in the `/etc/rc.d/rc5.d/` directory to determine which processes to start and stop. Below is an example listing for a runlevel 5, `/etc/rc.d/rc5.d/` directory:

```
K01pppoe -> ../init.d/pppoe
K05innd -> ../init.d/innd
K10ntpd -> ../init.d/ntpd
K15httpd -> ../init.d/httpd
K15mysqld -> ../init.d/mysqld
K15pvmd -> ../init.d/pvmd
K16rarpd -> ../init.d/rarpd
K20bootparamd -> ../init.d/bootparamd
K20nfs -> ../init.d/nfs
K20rstatd -> ../init.d/rstatd
K20rusersd -> ../init.d/rusersd
K20rwalld -> ../init.d/rwalld
K20rwhod -> ../init.d/rwhod
K25squid -> ../init.d/squid
K28amd -> ../init.d/amd
K30mcsvr -> ../init.d/mcserve
K34yppasswdd -> ../init.d/yppasswdd
K35dhcpcd -> ../init.d/dhcpcd
K35smb -> ../init.d/smb
K35vncserver -> ../init.d/vncserver
K45arpwatch -> ../init.d/arpwatch
K45named -> ../init.d/named
K50snmpd -> ../init.d/snmpd
K54pxe -> ../init.d/pxe
K55routed -> ../init.d/routed
K60mars-nwe -> ../init.d/mars-nwe
K61ldap -> ../init.d/ldap
K65kadmin -> ../init.d/kadmin
K65kprop -> ../init.d/kprop
K65krb524 -> ../init.d/krb524
K65krb5kdc -> ../init.d/krb5kdc
K75gated -> ../init.d/gated
K80nscd -> ../init.d/nscd
K84ypserv -> ../init.d/ypserv
K90ups -> ../init.d/ups
K96irda -> ../init.d/irda
S05kudzu -> ../init.d/kudzu
S06reconfig -> ../init.d/reconfig
S08ipchains -> ../init.d/ipchains
S10network -> ../init.d/network
S12syslog -> ../init.d/syslog
S13portmap -> ../init.d/portmap
S14nfslock -> ../init.d/nfslock
S18autofs -> ../init.d/autofs
S20random -> ../init.d/random
S25netfs -> ../init.d/netfs
S26apmd -> ../init.d/apmd
S35identd -> ../init.d/identd
```

```

S40atd -> ../init.d/atd
S45pcmcia -> ../init.d/pcmcia
S55sshd -> ../init.d/sshd
S56rawdevices -> ../init.d/rawdevices
S56xinetd -> ../init.d/xinetd
S60lpd -> ../init.d/lpd
S75keytable -> ../init.d/keytable
S80isdn -> ../init.d/isdn
S80sendmail -> ../init.d/sendmail
S85gpm -> ../init.d/gpm
S90canna -> ../init.d/canna
S90crond -> ../init.d/crond
S90FreeWnn -> ../init.d/FreeWnn
S90xfs -> ../init.d/xfs
S95anacron -> ../init.d/anacron
S95firstboot -> ../init.d/firstboot
S97rhnssd -> ../init.d/rhnssd
S99local -> ../rc.local
S99mdmonitor -> ../init.d/mdmonitor

```

As you can see, none of the scripts that actually start and stop the services are located in the `/etc/rc.d/rc5.d/` directory. Rather, all of the files in `/etc/rc.d/rc5.d/` are *symbolic links* pointing to scripts located in the `/etc/rc.d/init.d/` directory. Symbolic links are used in each of the `rc` directories so that the runlevels can be reconfigured by creating, modifying, and deleting the symbolic links without affecting the actual scripts they reference.

The name of each symbolic link begin with either a `K` or an `S`. The `K` links are processes that are killed on that runlevel, while those beginning with an `S` are started.

The `init` command first stops all of the `K` symbolic links in the directory by issuing the `/etc/rc.d/init.d/<command> stop` command, where `<command>` is the process to be killed. It then starts all of the `S` symbolic links by issuing `/etc/rc.d/init.d/<command> start`.

Tip

After the system is finished booting, you can log in as root and execute these same scripts to start and stop services. For instance, the command `/etc/rc.d/init.d/httpd stop` will stop the Apache Web server.

Each of the symbolic links are numbered to dictate start order. You can change the order in which the services are started or stopped by changing this number. Those symbolic links with the same number are started alphabetically.

In the example `/etc/rc.d/rc5.d/` directory above, the `init` command will kill `pppoe`, `innd`, `ntpd`, `httpd`, `mysqld`, `pvmd`, `rarpd`, `bootparamd`, `nfs`, `rstatd`, `rusersd`, `rwalld`, `rwhod`, `squid`, `amd`, `mcserv`, `yppasswdd`, `dhcpd`, `smb`, `vncserver`, `arpwatch`, `named`, `snmpd`, `pxe`, `routed`, `mars-nwe`, `ldap`, `kadmin`, `kprop`, `krb524`, `krb5kdc`, `gated`, `nsdc`, `ypserv`, `ups`, and `irda`.

After all processes are killed, `init` looks into the same directory and finds start scripts for `kudzu`, `reconfig`, `ipchains`, `portmap`, `nfslock`, `autofs`, `random`, `netfs`, `apmd`, `identd`, `atd`, `pcmcia`, `sshd`, `rawdevices`, `xinetd`, `lpd`, `keytable`, `isdn`, `sendmail`, `gpm`, `canna`, `crond`, `FreeWnn`, `xfs`, `anacron`, `firstboot`, `rhnssd`, and `mdmonitor`.

The last thing the `init` program does is run any scripts located in `/etc/rc.d/rc.local` (see Section 3.3 for more on customizing the `rc.local` file). At this point, the system is considered to be operating at runlevel 5.

After the `init` command has progressed through the appropriate `rc` directory for the runlevel, the `/etc/inittab` script forks a `getty` process for each virtual console (login prompts) allocated to the runlevel. Runlevels 2 through 5 get all six virtual consoles, while runlevel 1 (single user mode) gets only one and runlevels 0 and 6 get none. The `getty` process opens communication pathways to `tty` devices⁴, sets their modes, prints the login prompt, gets the user name, and initiates the login process for the user.

In runlevel 5, `/etc/inittab` runs a script called `/etc/X11/prefdm`. The `prefdm` script runs the preferred X display manager, `gdm` if you are running GNOME or `kdm` if you are running KDE, based on the contents of the `/etc/sysconfig/desktop/` directory.

Finally, the `init` command runs the `/etc/rc.d/rc.local` script.

At this point, you should be looking at a login prompt.

3.3. Running Programs at Boot Time

The file `/etc/rc.d/rc.local` script is run by the `init` command at boot time, or when changing runlevels, after all other initialization is complete. You can use this file to add additional commands necessary for your environment. For instance, you can start additional daemons or initialize a printer.

In addition, if you require serial ports setup at boot time, you can create and edit `/etc/rc.serial`. This script runs `setserial` commands to configure the system's serial ports. See the `setserial` man page for more information.

3.4. Differences in the Boot Process of Other Architectures

Once the Red Hat Linux kernel loads and hands off the boot process to the `init` command, the same sequence of events occurs on every architecture. So the main difference between each architecture's boot process is in the application used to find and load the kernel.

For example, the Alpha architecture uses the `aboot` boot loader, while the Itanium architecture uses the `ELILO` boot loader.

Consult the Official Red Hat Linux Installation Guide specific to these platforms for information on configuring their boot loaders.

3.5. SysV Init

The `SysV init` is a standard process used by Red Hat Linux to control which software the `init` command launches or shuts off on a given runlevel. `SysV init` is chosen because it is easier to use and more flexible than the traditional BSD style `init` process.

The configuration files for `SysV init` are in the `/etc/rc.d/` directory. Within this directory, are the `rc`, `rc.local`, and `rc.sysinit` scripts as well as the following directories:

```
init.d
rc0.d
rc1.d
rc2.d
rc3.d
rc4.d
rc5.d
rc6.d
```

4. See Section 2.3.11 for more information on `tty` devices.

The `init.d` directory contains the scripts used by the `init` command when controlling services. Each of the numbered directories represent the six default runlevels configured by default under Red Hat Linux. For more information on runlevels, see Section 3.6.

The default runlevel is listed in `/etc/inittab`. To find out the default runlevel for your system, look for the line similar to the one below near the top of `/etc/inittab`:

```
id:3:initdefault:
```

The default runlevel listed in the example above is three, as the number after the first colon indicates. If you want to change it, edit `/etc/inittab` as root.

Warning

Be very careful when editing `/etc/inittab`. Simple typos can cause your system to become unbootable. If this happens, you will either need a boot diskette for your system or you will need to enter rescue mode to boot your computer and fix the file.

For more information on rescue mode, see the chapter titled *Rescue Mode* in the *Official Red Hat Linux Customization Guide*.

3.6. Init Runlevels

The idea behind operating different services at different runlevels revolves around the fact that different systems can be used in a different ways. Some services cannot be used until the system is in a particular state, or *mode*, such as ready for more than one user or has networking available.

There are times in which you may want to operate the system at a lower mode, such as fixing disk corruption problems in runlevel 1, when no other users can possibly be on the system or leaving a server in runlevel 3 without an X session running. In these cases, running services that depend upon a higher system mode to function does not make sense because they will not work correctly anyway. By already having each service assigned to start when its particular runlevel is reached, you ensure an orderly start up process and can quickly change the mode of the machine without worrying about which services to manually start or stop.

Generally, Red Hat Linux operates in runlevel 3 or runlevel 5 — both full multi-user modes. The following runlevels are defined in Red Hat Linux:

- 0 — Halt
- 1 — Single-user mode
- 2 — Not used (user-definable)
- 3 — Full multi-user mode
- 4 — Not used (user-definable)
- 5 — Full multi-user mode (with an X-based login screen)
- 6 — Reboot

The default runlevel for a system to boot into and stop is configured in `/etc/inittab`. For more information on `/etc/inittab`, see Section 3.5.

Feel free to configure runlevels 2 and 4 as you see fit. Many users configure those runlevels in a way that makes the most sense for them while leaving the standard runlevels 3 and 5 alone. This allows

them to quickly move in and out of their custom configuration without disturbing the normal set of features at the standard runlevels.

If your machine gets into a state where it will not boot due to a bad `/etc/inittab` or will not let you log in because you have a corrupted `/etc/passwd` or if you have simply forgotten your password, you can boot into single-user mode.

If you are using LILO, you can enter single-user mode by typing **linux single** at the `LILO boot :` prompt.

If you are using GRUB as your boot loader, you can enter single-user mode using the following steps.

- In the graphical GRUB boot loader screen, select the **Red Hat Linux** boot label and press [e] to edit it.
- Arrow down to the kernel line and press [e] to edit it.
- At the prompt, type **single** and press [Enter].
- You will be returned to the GRUB screen with the kernel information. Press the [b] key to boot the system into single user mode.

A very bare system will boot, and you will have a command shell from which you can fix things.

If this does not work, you will need to boot by typing **linux init=/bin/bash** at the `LILO boot :` prompt. This places you at a shell prompt; note that no file systems other than the root file system are mounted, and the root file system is mounted in read-only mode. To mount it in read-write mode (to allow editing of a broken `/etc/inittab`, for example) do:

```
mount -n /proc
mount -o rw,remount /
```

3.6.1. Initscript Utilities

The `/sbin/chkconfig` utility is a simple command-line tool for maintaining the `/etc/rc.d/init.d` directory hierarchy. It relieves system administrators from having to directly manipulate the numerous symbolic links in the directories under `/etc/rc.d`.

In addition, there is `/sbin/ntsysv` that provides a text-based interface, which you may find easier to use than `chkconfig`'s command-line interface.

If you prefer a graphical interface, use the **Services Configuration Tool** program, which can be invoked using the `redhat-config-services` command.

All of these utilities must be run as root.

Please refer to the chapter titled *Controlling Access to Services in Official Red Hat Linux Customization Guide* for more information regarding these tools.

Next, we will discuss information in the files within the `/etc/sysconfig/` directory which define the parameters used by some services when they start up.

3.7. The `/etc/sysconfig/` Directory

The following information outlines some of the files found in the `/etc/sysconfig/` directory, their function, and their contents. This information is not intended to be complete, as many of these files have a variety of options that are only used in very specific or rare circumstances.

The `/usr/share/doc/initscripts-<version-number>/sysconfig.txt` file contains a more authoritative listing of the files found in the `/etc/sysconfig` directory and the configuration options available.

3.7.1. Files in the `/etc/sysconfig/` Directory

The following files are normally found in the `/etc/sysconfig/` directory:

- `amd`
- `apmd`
- `arpwatch`
- `authconfig`
- `cipe`
- `clock`
- `desktop`
- `dhcpd`
- `firstboot`
- `gpm`
- `harddisks`
- `hwconf`
- `i18n`
- `identd`
- `init`
- `ipchains`
- `iptables`
- `irda`
- `keyboard`
- `kudzu`
- `mouse`
- `named`
- `netdump`
- `network`
- `ntpd`
- `pcmcia`
- `radvd`
- `rawdevices`
- `redhat-config-users`
- `redhat-logviewer`
- `samba`
- `sendmail`
- `soundcard`
- `squid`
- `tux`
- `ups`

- `vncservers`
- `xinetd`

It is possible that your system may be missing a few of them if the corresponding program that would need that file is not installed.

Next, we will take a look at each one.

3.7.1.1. `/etc/sysconfig/amd`

The `/etc/sysconfig/amd` file contains various parameters used by `amd` allowing for the automounting and automatic unmounting of file systems.

3.7.1.2. `/etc/sysconfig/apmd`

The `/etc/sysconfig/apmd` file is used by `apmd` as a configuration for what things to start/stop/change on suspend or resume. It is set up to turn on or off `apmd` during startup, depending on whether your hardware supports *Advanced Power Management (APM)* or if you choose not to use it. `apm` is a monitoring daemon that works with power management code within the Linux kernel. It can alert you to a low battery if you are using Red Hat Linux on a laptop, among other things.

3.7.1.3. `/etc/sysconfig/arpwatch`

The `/etc/sysconfig/arpwatch` file is used to pass arguments to the `arpwatch` daemon at boot time. The `arpwatch` daemon maintains a table of Ethernet MAC addresses and their IP address pairings. For more information about what parameters you can use in this file, type `man arpwatch`. By default, this file sets the owner of the `arpwatch` process to the user `pcap`.

3.7.1.4. `/etc/sysconfig/authconfig`

The `/etc/sysconfig/authconfig` file sets the kind of authorization to be used on the host. It contains one or more of the following lines:

- `USEMD5=<value>`, where `<value>` is one of the following:
 - `yes` — MD5 is used for authentication.
 - `no` — MD5 is not used for authentication.
- `USEKERBEROS=<value>`, where `<value>` is one of the following:
 - `yes` — Kerberos is used for authentication.
 - `no` — Kerberos is not used for authentication.
- `USELDAPAUTH=<value>`, where `<value>` is one of the following:
 - `yes` — LDAP is used for authentication.
 - `no` — LDAP is not used for authentication.

3.7.1.5. `/etc/sysconfig/clock`

The `/etc/sysconfig/clock` file controls the interpretation of values read from the system clock. Earlier releases of Red Hat Linux used the following values (which are deprecated):

- `CLOCKMODE=<value>`, where `<value>` is one of the following:
 - `GMT` — Indicates that the clock is set to Universal Time (Greenwich Mean Time).
 - `ARC` — Indicates the ARC console's 42-year time offset is in effect (for Alpha-based systems only).

Currently, the correct values are:

- `UTC=<value>`, where `<value>` is one of the following boolean values:
 - `true` — Indicates that the clock is set to Universal Time. Any other value indicates that it is set to local time.
- `ARC=<value>`, where `<value>` is the following:
 - `true` — Indicates the ARC console's 42-year time offset is in effect. Any other value indicates that the normal UNIX epoch is assumed (for Alpha-based systems only).
- `ZONE=<filename>` — Indicates the timezone file under `/usr/share/zoneinfo` that `/etc/localtime` is a copy of, such as:
`ZONE="America/New York"`

3.7.1.6. `/etc/sysconfig/desktop`

The `/etc/sysconfig/desktop` file specifies the desktop manager to be run, such as:

```
DESKTOP="GNOME"
```

3.7.1.7. `/etc/sysconfig/dhcpd`

The `/etc/sysconfig/dhcpd` file is used to pass arguments to the `dhcpd` daemon at boot time. The `dhcpd` daemon implements the Dynamic Host Configuration Protocol (DHCP) and the Internet Bootstrap Protocol (BOOTP). DHCP and BOOTP assign hostnames to machines on the network. For more information about what parameters you can use in this file, type `man dhcpd`.

3.7.1.8. `/etc/sysconfig/firstboot`

Beginning with Red Hat Linux 8.0, the first time you boot the system, the `/sbin/init` program calls the `etc/rc.d/init.d/firstboot` script. This allows the user to install additional applications and documentation before the boot process completes.

The `/etc/sysconfig/firstboot` file tells the `firstboot` command not to run on subsequent reboots. If you want `firstboot` to run the next time you boot the system, simply remove `/etc/sysconfig/firstboot` and execute `chkconfig --level 5 firstboot on`.

3.7.1.9. `/etc/sysconfig/gpm`

The `/etc/sysconfig/gpm` file is used to pass arguments to the `gpm` daemon at boot time. The `gpm` daemon is the mouse server which allows mouse acceleration and middle-click pasting. For more information about what parameters you can use in this file, type `man gpm`. By default, it sets the mouse device to `/dev/mouse`.

3.7.1.10. `/etc/sysconfig/harddisks`

The `/etc/sysconfig/harddisks` file allows you to tune your hard drive(s). You can also use `/etc/sysconfig/hardiskhd[a-h]`, to configure parameters for specific drives.

Warning

Do not make changes to this file lightly. If you change the default values stored here, you could corrupt all of the data on your hard drive(s).

The `/etc/sysconfig/harddisks` file may contain the following:

- `USE_DMA=1`, where setting this to 1 enables DMA. However, with some chipsets and hard drive combinations, DMA can cause data corruption. *Check with your hard drive documentation or manufacturer before enabling this.*
- `Multiple_IO=16`, where a setting of 16 allows for multiple sectors per I/O interrupt. When enabled, this feature reduces operating system overhead by 30-50%. *Use with caution.*
- `EIDE_32BIT=3` enables (E)IDE 32-bit I/O support to an interface card.
- `LOOKAHEAD=1` enables drive read-lookahead.
- `EXTRA_PARAMS=` specifies where extra parameters can be added.

3.7.1.11. `/etc/sysconfig/hwconf`

The `/etc/sysconfig/hwconf` file lists all the hardware that `kudzu` detected on your system, as well as the drivers used, vendor ID and device ID information. The `kudzu` program detects and configures new and/or changed hardware on a system. The `/etc/sysconfig/hwconf` file is not meant to be manually edited. If you do edit it, devices could suddenly show up as being added or removed.

3.7.1.12. `/etc/sysconfig/i18n`

The `/etc/sysconfig/i18n` file sets the default language, such as:

```
LANG="en_US"
```

3.7.1.13. `/etc/sysconfig/identd`

The `/etc/sysconfig/identd` file is used to pass arguments to the `identd` daemon at boot time. The `identd` daemon returns the username of processes with open TCP/IP connections. Some services on the network, such as FTP and IRC servers, will complain and cause slow responses if `identd` is not running. But in general, `identd` is not a required service, so if security is a concern, you should not run it. For more information about what parameters you can use in this file, type `man identd`. By default, the file contains no parameters.

3.7.1.14. /etc/sysconfig/init

The `/etc/sysconfig/init` file controls how the system will appear and function during the boot process.

The following values may be used:

- `BOOTUP=<value>`, where `<value>` is one of the following:
 - `BOOTUP=color` means the standard color boot display, where the success or failure of devices and services starting up is shown in different colors.
 - `BOOTUP=verbose` means an old style display, which provides more information than purely a message of success or failure.
 - Anything else means a new display, but without ANSI-formatting.
- `RES_COL=<value>`, where `<value>` is the number of the column of the screen to start status labels. Defaults to 60.
- `MOVE_TO_COL=<value>`, where `<value>` moves the cursor to the value in the `RES_COL` line. Defaults to ANSI sequences output by `echo -e`.
- `SETCOLOR_SUCCESS=<value>`, where `<value>` sets the color to a color indicating success. Defaults to ANSI sequences output by `echo -e`, setting the color to green.
- `SETCOLOR_FAILURE=<value>`, where `<value>` sets the color to a color indicating failure. Defaults to ANSI sequences output by `echo -e`, setting the color to red.
- `SETCOLOR_WARNING=<value>`, where `<value>` sets the color to a color indicating warning. Defaults to ANSI sequences output by `echo -e`, setting the color to yellow.
- `SETCOLOR_NORMAL=<value>`, where `<value>` sets the color to 'normal'. Defaults to ANSI sequences output by `echo -e`.
- `LOGLEVEL=<value>`, where `<value>` sets the initial console logging level for the kernel. The default is 7; 8 means everything (including debugging); 1 means nothing except kernel panics. `syslogd` will override this once it starts.
- `PROMPT=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — Enables the key check for interactive mode.
 - `no` — Disables the key check for interactive mode.

3.7.1.15. /etc/sysconfig/ipchains

The `/etc/sysconfig/ipchains` file contains information used by the kernel to set up `ipchains` packet filtering rules at boot time or whenever the service is started.

This file is modified by typing the command `/sbin/service ipchains save` when valid `ipchains` rules are in place. You should not manually edit this file. Instead, use the `/sbin/ipchains` command to configure the necessary packet filtering rules and then save the rules to this file using `/sbin/service ipchains save`.

Use of `ipchains` to set up firewall rules is not recommended as it is deprecated and may disappear from future releases of Red Hat Linux. If you need a firewall, you should use `iptables` instead.

3.7.1.16. `/etc/sysconfig/iptables`

Like `/etc/sysconfig/ipchains`, the `/etc/sysconfig/iptables` file stores information used by the kernel to set up packet filtering services at boot time or whenever the service is started.

You should not modify this file by hand unless you are familiar with how to construct `iptables` rules. The simplest way to add rules is to use the `/usr/sbin/lokkit` command or the **gnome-lokkit** graphical application to create your firewall. Using these applications will automatically edit this file at the end of the process.

If you wish, you can manually create rules using `/sbin/iptables` and then type `/sbin/service iptables save` to add the rules to the `/etc/sysconfig/iptables` file.

Once this file exists, any firewall rules saved there will persist through a system reboot or a service restart.

For more information on `iptables` see Chapter 13.

3.7.1.17. `/etc/sysconfig/irda`

The `/etc/sysconfig/irda` file controls how infrared devices on your system are configured at startup.

The following values may be used:

- `IRDA=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — `irattach` will be run, which periodically checks to see if anything is trying to connect to the infrared port, such as another notebook computer trying to make a network connection. For infrared devices to work on your system, this line must be set to `yes`.
 - `no` — `irattach` will not be run, preventing infrared device communication.
- `DEVICE=<value>`, where `<value>` is the device (usually a serial port) that handles infrared connections.
- `DONGLE=<value>`, where `<value>` specifies the type of dongle being used for infrared communication. This setting exists for people who use serial dongles rather than real infrared ports. A dongle is a device that is attached to a traditional serial port to communicate via infrared. This line is commented out by default because notebooks with real infrared ports are far more common than computers with add-on dongles.
- `DISCOVERY=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — Starts `irattach` in discovery mode, meaning it actively checks for other infrared devices. This needs to be turned on for the machine to be actively looking for an infrared connection (meaning the peer that does not initiate the connection).
 - `no` — Does not start `irattach` in discovery mode.

3.7.1.18. `/etc/sysconfig/keyboard`

The `/etc/sysconfig/keyboard` file controls the behavior of the keyboard. The following values may be used:

- `KEYBOARDTYPE=sun|pc`, which is used on SPARCs only. `sun` means a Sun keyboard is attached on `/dev/kbd`, and `pc` means a PS/2 keyboard connected to a PS/2 port.
- `KEYTABLE=<file>`, where `<file>` is the name of a keytable file.

For example: `KEYTABLE="us"`. The files that can be used as keytables start in `/usr/lib/kbd/keymaps/i386` and branch into different keyboard layouts from there, all labeled `<file>.kmap.gz`. The first file found beneath `/usr/lib/kbd/keymaps/i386` that matches the `KEYTABLE` setting is used.

3.7.1.19. `/etc/sysconfig/kudzu`

The `/etc/sysconfig/kudzu` allows you to specify a safe probe of your system's hardware by `kudzu` at boot time. A safe probe is one that disables serial port probing.

- `SAFE=<value>`, where `<value>` is one of the following:
 - `yes` — `kudzu` does a safe probe.
 - `no` — `kudzu` does a normal probe.

3.7.1.20. `/etc/sysconfig/mouse`

The `/etc/sysconfig/mouse` file is used to specify information about the available mouse. The following values may be used:

- `FULLNAME=<value>`, where `<value>` refers to the full name of the kind of mouse being used.
- `MOUSETYPE=<value>`, where `<value>` is one of the following:
 - `microsoft` — A Microsoft™ mouse.
 - `mouseman` — A MouseMan™ mouse.
 - `mousesystems` — A Mouse Systems™ mouse.
 - `ps/2` — A PS/2 mouse.
 - `msbm` — A Microsoft™ bus mouse.
 - `logibm` — A Logitech™ bus mouse.
 - `atibm` — An ATI™ bus mouse.
 - `logitech` — A Logitech™ mouse.
 - `mmseries` — An older MouseMan™ mouse.
 - `mmhittab` — An mmhittab mouse.
- `XEMU3=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — The mouse only has two buttons, but three mouse buttons should be emulated.
 - `no` — The mouse already has three buttons.
- `XMOUSETYPE=<value>`, where `<value>` refers to the kind of mouse used when X is running. The options here are the same as the `MOUSETYPE` setting in this same file.
- `DEVICE=<value>`, where `<value>` is the mouse device.

In addition, `/dev/mouse` is a symbolic link that points to the actual mouse device.

3.7.1.21. /etc/sysconfig/named

The `/etc/sysconfig/named` file is used to pass arguments to the `named` daemon at boot time. The `named` daemon is a *Domain Name System (DNS)* server which implements the *Berkeley Internet Name Domain (BIND)* version 9 distribution. This server maintains a table of which hostnames are associated with IP addresses on the network.

Currently, only the following values may be used:

- `ROOTDIR="/<some/where>"`, where `<some/where>` refers to the full directory path of a configured `chroot` environment under which `named` will run. This `chroot` environment must first be configured. Type `info chroot` for more information on how to do this.
- `OPTIONS="<value>"`, where `<value>` any option listed in the man page for `named` except `-t`. In place of `-t`, use the `ROOTDIR` line above instead.

For more information about what parameters you can use in this file, type `man named`. For detailed information on how to configure a BIND DNS server, see Chapter 16. By default, the file contains no parameters.

3.7.1.22. /etc/sysconfig/netdump

The `/etc/sysconfig/netdump` file is the configuration file for the `/etc/init.d/netdump` service. The `netdump` service sends both oops data and memory dumps over the network. In general, `netdump` is not a required service, so you should only run it if you absolutely need to. For more information about what parameters you can use in this file, type `man netdump`.

3.7.1.23. /etc/sysconfig/network

The `/etc/sysconfig/network` file is used to specify information about the desired network configuration. The following values may be used:

- `NETWORKING=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — Networking should be configured.
 - `no` — Networking should not be configured.
- `HOSTNAME=<value>`, where `<value>` should be the *Fully Qualified Domain Name (FQDN)*, such as `hostname.domain.com`, but can be whatever hostname you want.

Note

For compatibility with older software that people might install (such as `trn`), the `/etc/HOSTNAME` file should contain the same value as here.

- `GATEWAY=<value>`, where `<value>` is the IP address of the network's gateway.
- `GATEWAYDEV=<value>`, where `<value>` is the gateway device, such as `eth0`.
- `NISDOMAIN=<value>`, where `<value>` is the NIS domain name.

3.7.1.24. `/etc/sysconfig/ntpd`

The `/etc/sysconfig/ntpd` file is used to pass arguments to the `ntpd` daemon at boot time. The `ntpd` daemon sets and maintains the system clock to synchronize with an Internet standard time server. It implements version 4 of the Network Time Protocol (NTP). For more information about what parameters you can use in this file, point a browser at the following file: `/usr/share/doc/ntp-<version>/ntpd.htm` (where `<version>` is the version number of `ntpd`). By default, this file sets the owner of the `ntpd` process to the user `ntp`.

3.7.1.25. `/etc/sysconfig/pcmcia`

The `/etc/sysconfig/pcmcia` file is used to specify PCMCIA configuration information. The following values may be used:

- `PCMCIA=<value>`, where `<value>` is one of the following:
 - `yes` — PCMCIA support should be enabled.
 - `no` — PCMCIA support should not be enabled.
- `PCIC=<value>`, where `<value>` is one of the following:
 - `i82365` — The computer has an i82365-style PCMCIA socket chipset.
 - `tcic` — The computer has a tcic-style PCMCIA socket chipset.
- `PCIC_OPTS=<value>`, where `<value>` is the socket driver (i82365 or tcic) timing parameters.
- `CORE_OPTS=<value>`, where `<value>` is the list of `pcmcia_core` options.
- `CARDMGR_OPTS=<value>`, where `<value>` is the list of options for the PCMCIA `cardmgr` (such as `-q` for quiet mode; `-m` to look for loadable kernel modules in the specified directory, and so on). Read the `cardmgr` man page for more information.

3.7.1.26. `/etc/sysconfig/radvd`

The `/etc/sysconfig/radvd` file is used to pass arguments to the `radvd` daemon at boot time. The `radvd` daemon listens to for router requests and sends router advertisements for the IP version 6 protocol. This service allows hosts on a network to dynamically change their default routers based on these router advertisements. For more information about what parameters you can use in this file, type `man radvd`. By default, this file sets the owner of the `radvd` process to the user `radvd`.

3.7.1.27. `/etc/sysconfig/rawdevices`

The `/etc/sysconfig/rawdevices` file is used to configure raw device bindings, such as:

```
/dev/raw/raw1 /dev/sda1
/dev/raw/raw2 8 5
```

3.7.1.28. `/etc/sysconfig/redhat-config-users`

The `/etc/sysconfig/redhat-config-users` file is the configuration file for the graphical application, **User Manager**. Under Red Hat Linux 8.0 this file is used to filter out system users such as root, daemon, or lp. This file is edited by the **Preferences => Filter system users and groups** pull-down menu in the **User Manager** application and should not be edited by hand. For more information on using this application, see the chapter called *User and Group Configuration* in the *Official Red Hat Linux Customization Guide*.

3.7.1.29. `/etc/sysconfig/redhat-logviewer`

The `/etc/sysconfig/redhat-logviewer` file is the configuration file for the graphical, interactive log viewing application, **Log Viewer**. This file is edited by the **Edit => Preferences** pull-down menu in the **Log Viewer** application and should not be edited by hand. For more information on using this application, see the chapter called *Log Files* in the *Official Red Hat Linux Customization Guide*.

3.7.1.30. `/etc/sysconfig/samba`

The `/etc/sysconfig/samba` file is used to pass arguments to the `smbd` and the `nmbd` daemons at boot time. The `smbd` daemon offers file sharing connectivity for Windows clients on the network. The `nmbd` daemon offers NetBIOS over IP naming services. For more information about what parameters you can use in this file, type `man smbd`. By default, this file sets `smbd` and `nmbd` to run in daemon mode.

3.7.1.31. `/etc/sysconfig/sendmail`

The `/etc/sysconfig/sendmail` file allows messages to be sent to one or more recipients, routing the message over whatever networks are necessary. The file sets the default values for the **Sendmail** application to run. Its default values are to run as a background daemon, and to check its queue once an hour in case something has backed up.

The following values may be used:

- `DAEMON=<value>`, where `<value>` is one of the following boolean values:
 - `yes` — **Sendmail** should be configured to listen to port 25 for incoming mail. `yes` implies the use of **Sendmail**'s `-bd` options.
 - `no` — **Sendmail** should not be configured to listen to port 25 for incoming mail.
- `QUEUE=1h` which is given to **Sendmail** as `-q$QUEUE`. The `-q` option is not given to **Sendmail** if `/etc/sysconfig/sendmail` exists and `QUEUE` is empty or undefined.

3.7.1.32. `/etc/sysconfig/soundcard`

The `/etc/sysconfig/soundcard` file is generated by `sndconfig` and should not be modified. The sole use of this file is to determine what card entry in the menu to pop up by default the next time `sndconfig` is run. Sound card configuration information is located in the `/etc/modules.conf` file.

It may contain the following:

- `CARDTYPE=<value>`, where `<value>` is set to, for example, `SB16` for a Soundblaster 16 sound card.

3.7.1.33. `/etc/sysconfig/squid`

The `/etc/sysconfig/squid` file is used to pass arguments to the `squid` daemon at boot time. The `squid` daemon is a proxy caching server for Web client applications. For more information on configuring a `squid` proxy server, use a Web browser to open the `/usr/share/doc/squid-<version>/` directory (replace `<version>` with the `squid` version number installed on your system). By default, this file sets `squid` to start in daemon mode and sets the amount of time before it shuts itself down.

3.7.1.34. `/etc/sysconfig/tux`

The `/etc/sysconfig/tux` file is the configuration file for the Red Hat Content Accelerator (formerly known as TUX), the kernel-based web server. For more information on configuring the Red Hat Content Accelerator, use a Web browser to open the `/usr/share/doc/tux-<version>/tux/index.html` (replace `<version>` with the version number of TUX installed on your system). The parameters available for this file are listed in `/usr/share/doc/tux-<version>/tux/parameters.html`.

3.7.1.35. `/etc/sysconfig/ups`

The `/etc/sysconfig/ups` file is used to specify information about any *Uninterruptible Power Supplies (UPS)* connected to your system. A UPS can be very valuable for a Red Hat Linux system because it gives you time to correctly shut down the system in the case of power interruption. The following values may be used:

- `SERVER=<value>`, where `<value>` is one of the following:
 - `yes` — A UPS device is connected to your system.
 - `no` — A UPS device is not connected to your system.
- `MODEL=<value>`, where `<value>` must be one of the following or set to `NONE` if no UPS is connected to the system:
 - `apcsmart` — For a APC SmartUPS™ or similar device.
 - `fentonups` — For a Fenton UPS™.
 - `optiups` — For an OPTI-UPS™ device.
 - `bestups` — For a Best Power™ UPS.
 - `genericups` — For a generic brand UPS.
 - `ups-trust425+625` — For a Trust™ UPS.
- `DEVICE=<value>`, where `<value>` specifies where the UPS is connected, such as `/dev/ttyS0`.
- `OPTIONS=<value>`, where `<value>` is a special command that needs to be passed to the UPS.

3.7.1.36. `/etc/sysconfig/vncservers`

The `/etc/sysconfig/vncservers` file configures the way the *Virtual Network Computing (VNC)* server starts up.

VNC is a remote display system which allows you to view a desktop environment not only on the machine where it is running but across different networks on a variety of architectures.

It may contain the following:

- `VNCSEVER=`<value>, where <value> is set to something like "1:fred", to indicate that a VNC server should be started for user fred on display :1. User fred must have set a VNC password using `vncpasswd` before attempting to connect to the remote VNC server.

Note that when you use a VNC server, your communication with it is unencrypted, and so it should not be used on an untrusted network. For specific instructions concerning the use of SSH to secure the VNC communication, please read the information found at <http://www.uk.research.att.com/vnc/sshvnc.html>. To find out more about SSH, see Chapter 9 or *Official Red Hat Linux Customization Guide*.

3.7.1.37. `/etc/sysconfig/xinetd`

The `/etc/sysconfig/xinetd` file is used to pass arguments to the `xinetd` daemon at boot time. The `xinetd` daemon starts programs that provide Internet services when a request to the port for that service is received. For more information about what parameters you can use in this file, type `man xinetd`. For more information on the `xinetd` service, see Section 8.3.

3.7.2. Directories in the `/etc/sysconfig/` Directory

The following directories are normally found in `/etc/sysconfig/` and a basic description of what they contain:

- `apm-scripts` — This contains the Red Hat APM suspend/resume script. You should not edit this file directly. If you need customization, simply create a file called `/etc/sysconfig/apm-scripts/apmcontinue` and it will be called at the end of the script. Also, you can control the script by editing `/etc/sysconfig/apmd`.
- `cbq` — This directory contains the configuration files needed to do Class Based Queuing for bandwidth management on network interfaces.
- `networking` — This directory is used by the **Network Administration Tool** (`redhat-config-network`) and its contents should not be edited manually. For more information about configuring network interfaces using the **Network Administration Tool**, see the chapter called *Network Configuration* in the *Official Red Hat Linux Customization Guide*.
- `network-scripts` — This directory contains the following network-related configuration files:
 - Network configuration files for each configured network interface, such as `ifcfg-eth0` for the `eth0` Ethernet interface.
 - Scripts used to bring up and down network interfaces, such as `ifup` and `ifdown`.
 - Scripts used to bring up and down ISDN interfaces, such as `ifup-isdn` and `ifdown-isdn`
 - Various shared network function scripts which should not be edited directly.

For more information on the `network-scripts` directory, see Chapter 12

- `rhn` — This directory contains the configuration files and GPG keys for the Red Hat Network. No files in this directory should be edited by hand. For more information on the Red Hat Network, see the Red Hat Network website at the following URL: <https://rhn.redhat.com>.

3.8. Shutting Down

To shut down Red Hat Linux, issue the `shutdown` command. You can read the `shutdown` man page for complete details, but the two most common uses are:

```
/sbin/shutdown -h now
/sbin/shutdown -r now
```

You must run `shutdown` as root. After shutting everything down, the `-h` option will halt the machine, and the `-r` option will reboot.

Non-root users can use the `reboot` and `halt` commands to shutdown the system while in runlevels 1 through 5. However, not all Linux operating systems support this feature.

If your computer does not power itself down, be careful not turn off the computer until you see a message indicating that the system is halted.

Failure to wait for this message means you may be turning off the machine before the hard drive partitions are unmounted, which can cause file system corruption

Boot Loaders

Before Red Hat Linux can run on a system, it must be started by special program called a *boot loader*. The boot loader program usually exists on the system's primary hard drive or other media device and is responsible for loading the Linux kernel its required files, or, in some cases, other operating systems into memory.

4.1. Boot Loaders and System Architecture

Each system architecture which can run Red Hat Linux uses a different boot loader. For example, the Alpha architecture uses the `aboot` boot loader, while the Itanium architecture uses the `ELILO` boot loader.

This chapter discuss commands and configuration options for the two boot loaders supplied with Red Hat Linux 8.0 for x86 architecture: GRUB and LILO.

4.2. GRUB

GNU GRand Unified Boot loader or GRUB is a program which enable the user to select which installed operating system or kernel to load at system boot time. It also allows the user to pass arguments to the kernel.

4.2.1. GRUB and the x86 Boot Process

This section will discuss in more detail the specific role GRUB plays when booting an x86 system. For a detailed look at the overall boot process, see Section 3.2.

GRUB loads itself into memory in the following stages:

1. *The Stage 1 or primary boot loader is read into memory by the BIOS from the MBR¹.* The primary boot loader exists on less than 512 bytes of disk space within the MBR. The only thing it does is load the Stage 1.5 or Stage 2 boot loader.
2. *The Stage 1.5 boot loader is read into memory by the Stage 1 boot loader only if necessary.* Some hardware requires an intermediate step to get to the Stage 2 boot loader. This is sometimes true when the `/boot` partition is above the 1024 cylinder head of the hard drive or when using LBA mode. The Stage 1.5 boot loader is found either on the `/boot` partition or on a small part of the MBR and the `/boot` partition.
3. *The Stage 2 or secondary boot loader is read into memory.* The secondary boot loader displays the GRUB menu and command environment. This interface allows you to select which operating system or Linux kernel to boot, pass arguments to the kernel, or look at system parameters, such as available RAM.
4. *The secondary boot loader reads the operating system or kernel and `initrd` into memory.* Once GRUB determines which operating system to start, it loads it into memory and hands control of the machine to that operating system.

The boot method used to boot Red Hat Linux is called the *direct loading* method because the boot loader loads the operating system directly. There is no intermediary between the boot loader and the kernel.

1. For more on the system BIOS and the MBR, see Section 3.2.1.

The boot process used by other operating systems may differ. For example, Microsoft's DOS and Windows operating systems, as well as various other proprietary operating systems, are loaded using a *chain loading* boot method. Under this method, the MBR simply points to the first sector of the partition holding the operating system. There it finds the files necessary to actually boot that operating system.

GRUB supports both direct and chain-loading boot methods, allowing it to boot almost any operating system.

Warning

During installation, Microsoft's DOS and Windows installer completely overwrites the MBR, destroying any existing boot loader. If creating a dual boot system, it is best to install the Microsoft operating system first. For instructions on how to do this, see the appendix titled *Installing Red Hat Linux in a Dual-Boot Environment* in the *Official Red Hat Linux Installation Guide*.

4.2.2. Features of GRUB

GRUB contains a number of features that make it preferable to other boot loaders available for the x86 architecture. Below is a list of some of the more important features:

- *GRUB provides a true command-based, pre-OS environment on x86 machines.* This affords the user maximum flexibility in loading operating systems with certain options or gathering information about the system. For years many non-x86 architectures have employed pre-OS environments that allow system booting from a command line. While some command features are available with LILO and other x86 boot loaders, GRUB is more feature rich.
- *GRUB supports Logical Block Addressing (LBA) mode.* LBA places the addressing conversion used to find files in the hard driver's firmware, and it is used on many IDE and all SCSI hard devices. Before LBA, boot loaders could encounter the 1024-cylinder BIOS limitation, where the BIOS could not find a file after that cylinder head of the disk. LBA support allows GRUB to boot operating systems from partitions beyond the 1024-cylinder limit, so long as the system BIOS supports LBA mode. Most modern BIOS revisions support LBA mode.
- *GRUB can read ext2 partitions.* This allows GRUB to access its configuration file, `/boot/grub/grub.conf`, every time the system boots, obviating the need for the user to write a new version of the first stage boot loader to MBR when configuration changes are made. The only time a user would need to reinstall GRUB on the MBR is if the physical location of the `/boot` partition is moved on the disk. For details on installing GRUB to the MBR, see Section 4.3.

4.3. Installing GRUB

If GRUB was not installed during the Red Hat Linux installation process, you can install it afterward and it will automatically become the default boot loader.

Before installing GRUB, you should make sure you have the latest GRUB package available or you can use the GRUB package from the Red Hat Linux installation CD-ROMs. For instructions on installing packages, see the chapter titled *Package Management with RPM* in the *Official Red Hat Linux Customization Guide*.

Once the GRUB package is installed, open a root shell prompt and run the command `/sbin/grub-install <location>`, where `<location>` is the location GRUB Stage 1 boot loader should be installed.

The following command installs GRUB to the MBR of the master IDE device on the primary IDE bus, also known as the C drive:

```
/sbin/grub-install /dev/hda
```

The next time you boot the system, you should see the GRUB graphical boot loader menu before the kernel loads.

4.4. GRUB Terminology

One of the most important things to understand before using GRUB is how the program refers to devices, such as hard drives and partitions. This information is particularly important when configuring GRUB to boot multiple operating systems.

4.4.1. Device Names

The first hard drive of a system is called `(hd0)` by GRUB. The first partition on that drive is called `(hd0, 0)`, and the fifth partition on the second hard drive is called `(hd1, 4)`. In general, the naming convention for file systems when using GRUB breaks down in this way:

```
(<type-of-device><bios-device-number>,<partition-number>)
```

The parentheses and comma are very important to the device naming conventions. The `<type-of-device>` refers to whether a hard disk (`hd`) or floppy disk (`fd`) is being specified.

The `<bios-device-number>` is the number of the device according to the system's BIOS, starting with 0. The primary IDE hard drive is numbered 0, while the secondary IDE hard drive is numbered 1. The ordering is roughly equivalent to the way the Linux kernel arranges the devices by letters, where the `a` in `hda` relates to 0, the `b` in `hdb` relates to 1, and so on.

Note

GRUB's numbering system for devices starts with 0, not 1. Failing to make this distinction is one of the most common mistakes made by new GRUB users.

The `<partition-number>` relates to the number of a specific partition on a disk device. Like the `<bios-device-number>`, the partition numbering starts at 0. While most partitions are specified by numbers, if a system uses BSD partitions, they are signified by letters, such as `a` or `c`.

GRUB uses the following rules when naming devices and partitions:

- It does not matter if system hard drives are IDE or SCSI. All hard drives start with `hd`. Floppy disks start with `fd`.
- To specify an entire device without respect to its partitions, simply leave off the comma and the partition number. This is important when telling GRUB to configure the MBR for a particular disk. For example, `(hd0)` specifies the MBR on the first device and `(hd3)` specifies the MBR on the fourth device.
- If a system has multiple drive devices, it is very important to know the drive boot order set in the BIOS. This is rather simple to do if a system has only IDE or SCSI drives, but if there is a mix of devices, it can become confusing.

4.4.2. File Names

When typing commands to GRUB involving a file, such as a menu list to use when allowing the booting of multiple operating systems, it is necessary to include the file immediately after specifying the device and partition. A sample file specification to an absolute filename is organized as follows:

```
(<type-of-device><bios-device-number>,<partition-number>)/path/to/file
```

Most of the time, a user will specify files by the directory path on that partition, plus the filename.

It is also possible to specify files to GRUB that do not actually appear in the filesystem, such as a chain loader that appears in the first few blocks of a partition. To specify these files, you must provide a *blocklist*, which tells GRUB, block by block, where the file is located in the partition. Since a file can be comprised of several different sets of blocks, there is a specific way to write blocklists. Each file's section location is described by an offset number of blocks and then a number of blocks from that offset point, and the sections are put together in a comma-delimited order.

Consider the following blocklist:

```
0+50,100+25,200+1
```

This blocklist tells GRUB to use a file that starts at the first block on the partition and uses blocks 0 through 49, 99 through 124, and 199.

Knowing how to write blocklists is useful when using GRUB to load operating systems that use chain loading, such as Microsoft Windows. It is possible to leave off the offset number of blocks if starting at block 0. As an example, the chain loading file in the first partition of the first hard drive would have the following name:

```
(hd0,0)+1
```

The following shows the `chainloader` command with a similar blocklist designation at the GRUB command line after setting the correct device and partition as root:

```
chainloader +1
```

4.4.3. GRUB's Root Filesystem

Some users are confused by the use of the term "root filesystem" with GRUB. It is important to remember that GRUB's root filesystem has nothing to do with the Linux root filesystem.

The GRUB root filesystem is the root partition for a particular device. GRUB uses this information to mount the device and load files from it.

With Red Hat Linux, once GRUB has loaded its root partition, which equates to the `/boot` partition and contains the Linux kernel, the `kernel` command can be executed with the location of the kernel file as an option. Once the Linux kernel boots, it sets its own root filesystem. The original GRUB root filesystem and its mounts are forgotten; they only existed to boot the kernel file.

Refer to the `root` and `kernel` commands in Section 4.6 for more information.

4.5. GRUB Interfaces

GRUB features three interfaces, which provide different levels of functionality. Each of these interfaces allows users to boot operating systems, and move between interfaces within the GRUB environment.

4.5.1. Menu Interface

If GRUB was automatically configured by the Red Hat Linux installation program, this is the interface shown by default. A menu of operating systems or kernels preconfigured with their own boot commands are displayed as a list, ordered by name. Use the arrow keys to select an option other than the default selection and press the [Enter] key to boot it. Alternatively, a timeout period is set, so that GRUB will start loading the default option.

From the menu interface, press the [e] key to enter the entry editor interface or the [c] key to load a command line interface.

See Section 4.7 for more information on configuring this interface.

4.5.2. Menu Entry Editor Interface

To access the menu entry editor, press the [e] key from the boot loader menu. The GRUB commands for that entry are displayed here, and users may alter these command lines before booting the operating system by adding a command line ([o] inserts the new line after the current line and [O] before it), editing one ([e]), or deleting one ([d]).

After all changes are made, hit the [b] key to execute the commands and boot the operating system. The [Esc] key discards any changes and reloads the standard menu interface. The [c] key will load the command line interface.

4.5.3. Command Line Interface

The command line is the most basic GRUB interface, but it is also the one that grants the most control. The command line makes it possible to type any relevant GRUB commands followed by the [Enter] key to execute them. This interface features some advanced shell-like features, including [Tab] key completion, based on context, and [Ctrl] key combinations when typing commands, such as [Ctrl]-[a] to move to the beginning of a line, and [Ctrl]-[e] to move to the end of a line. In addition, the arrow, [Home], [End], and [Delete] keys work as they do in the `bash` shell.

See Section 4.6, for a list of common commands.

4.5.4. Order of Interface Use

When the GRUB environment loads the second stage boot loader, it looks for its configuration file. When found, it uses the configuration file to build the menu list and displays the boot menu interface.

If the configuration file cannot be found, or if the configuration file is unreadable, GRUB will load the command line interface to allow users to manually type the commands necessary to boot an operating system.

If the configuration file is not valid, GRUB will print out the error and ask for input. This can be very helpful, because users will then be able to see precisely where the problem occurred and fix it in the file. Pressing any key will reload the menu interface, where it is then possible to edit the menu option and correct the problem based on the error reported by GRUB. If the correction fails, the error is reported and GRUB will begin again.

4.6. GRUB Commands

GRUB allows a number of useful commands in its command line interface. Some of the commands accept options after their name, and these options should be separated from the command and other options on that line by space characters.

The following is a list useful commands:

- `boot` — Boots the operating system or chain loader that has been previously specified and loaded.
- `chainloader <file-name>` — Loads the specified file as a chain loader. To grab the file at the first sector of the specified partition, use `+1` as the file's name.
- `displaymem` — Displays the current use of memory, based on information from the BIOS. This is useful to determine how much RAM a system has prior to booting it.
- `initrd <file-name>` — Enables users to specify an initial RAM disk to use when booting. An `initrd` is necessary when the kernel needs certain modules in order to boot properly, such as when the root partition is formatted with the ext3 file system.
- `install <stage-1> <install-disk> <stage-2> p <config-file>` — Installs GRUB to the system MBR.

Warning

The `install` command will overwrite any other information in the MBR. If executed, any information (other than GRUB information) that is used to boot other operating systems, will be lost.

Make sure you know what you are doing before executing this command.

This command can be configured in several different ways. However, it is required to specify a `<stage-1>`, which signifies a device, partition, and file where the first boot loader image can be found, such as `(hd0,0)/grub/stage1`. In addition, specify the disk where the stage 1 boot loader should be installed, such as `(hd0)`.

The `<stage-2>` section tells the stage 1 boot loader where the stage 2 boot loader is located, such as `(hd0,0)/grub/stage2`. The `p` option tells the `install` command that a menu configuration file is being specified in the `<config-file>` section, such as `(hd0,0)/grub/grub.conf`.

- `kernel <kernel-file-name> <option-1> <option-N>` — Specifies the kernel file to load from GRUB's root filesystem when using direct loading to boot the operating system. Options can follow the `kernel` command and will be passed to the kernel when it is loaded.

For Red Hat Linux, an example `kernel` command looks like the following:

```
kernel /vmlinuz root=/dev/hda5
```

This line specifies that the `vmlinuz` file is loaded from GRUB's root filesystem, such as `(hd0,0)`. An option is also passed to the kernel specifying that the root filesystem for the Linux kernel when it loads should be on `hda5`, the fifth partition on the first IDE hard drive. Multiple options may be placed after this option, if needed.

- `root <device-and-partition>` — Configures GRUB's root partition to be the particular device and partition, such as `(hd0,0)`, and mounts the partition so that files can be read.
- `rootnoverify <device-and-partition>` — Does the same thing as the `root` command but does not mount the partition.

Commands other than these are available. Type `info grub` for a full list of commands.

4.7. GRUB Menu Configuration File

The configuration file, which is used to create the list in GRUB's menu interface of operating systems to boot, essentially allows the user to select a pre-set group of commands to execute. The commands given in Section 4.6 can be used, as well as some special commands that are only available in the configuration file.

4.7.1. Special Configuration File Commands

The following commands can only be used in the GRUB menu configuration file:

- `color <normal-color> <selected-color>` — Allows for the set up specific colors to be used in the menu, where two colors are configured as the foreground and background. Use simple color names, such as `red/black`. For example:
`color red/black green/blue`
- `default <title-name>` — The default entry title name that will be loaded if the menu interface times out.
- `fallback <title-name>` — If used, the entry title name to try if first attempt fails.
- `hiddenmenu` — If used, prevents the GRUB menu interface from being displayed, loading the default entry when the `timeout` period expires. The user can see the standard GRUB menu by pressing the [Esc] key.
- `password <password>` — If used, prevents the user who does not know the password from editing the entries for this menu option.
 Optionally, it is possible to specify an alternate menu configuration file after the `<password>`, so that, if the password is known, GRUB will restart the second stage of the boot loader and use this alternate configuration file to build the menu. If this alternate file is left out of the command, then a user who knows the password would be able to edit the current configuration file.
- `timeout` — If used, sets the interval, in seconds, before GRUB loads the entry designated by the default command.
- `splashimage` — Specifies the location of the splash screen image to be used when GRUB boots.
- `title` — Sets a title to be used with a particular group of commands used to load an operating system.

The # character can be used to place comments in the menu configuration file.

4.7.2. Configuration File Structure

GRUB menu interface's configuration file is `/boot/grub/grub.conf`. The commands to set the global preferences for the menu interface are placed at the top of the file, followed by the different entries for each of the operating systems or kernels listed in the menu.

A very basic GRUB menu configuration file designed to boot either Red Hat Linux or Microsoft Windows 2000 might look as follows:

```
default=0
timeout=10
splashimage=(hd0,0)/grub/splash.xpm.gz

# section to load linux
title Red Hat Linux (2.4.18-5.47)
    root (hd0,0)
    kernel /vmlinuz-2.4.18-5.47 ro root=/dev/sda2
    initrd /initrd-2.4.18-5.47.img

# section to load Windows 2000
title windows
    rootnoverify (hd0,0)
    chainloader +1
```

This file would tell GRUB to build a menu with Red Hat Linux as the default operating system, set to autoboot it after 10 seconds. Two sections are given, one for each operating system entry, with commands specific to this system's disk partition table.

Note

Note the default is specified as a number. This refers to the first `title` line GRUB comes across. If you want `windows` to be the default, change the `default=` value to `1`.

Configuring a GRUB menu configuration file to boot multiple operating systems is beyond the scope of this chapter. Please consult Section 4.11 for detailed information about configuring GRUB to boot different operating systems.

4.8. LILO

LILO is an acronym for *LI*nux *LO*ader and has been used to boot Linux on x86 systems for many years. Although GRUB is now the default boot loader, some prefer to use LILO because it is more familiar to them and others use it out of necessity, since GRUB may have trouble booting some hardware.

4.8.1. LILO and the x86 Boot Process

This section will discuss in more detail the specific role LILO plays when booting an x86 system. For a detailed look at the overall boot process, see Section 3.2.

LILO loads itself into memory almost identically to GRUB, except it is only a two stage loader.

1. *The Stage 1 or primary boot loader is read into memory by the BIOS from the MBR².* The primary boot loader exists on less than 512 bytes of disk space within the MBR. The only thing it does is load the Stage 2 boot loader and pass to it disk geometry information.
2. *The Stage 2 or secondary boot loader is read into memory.* The secondary boot loader displays the Red Hat Linux initial screen. This screen allows you to select which operating system or Linux kernel to boot.
3. *The Stage 2 boot loader reads the operating system or kernel and `initrd` into memory.* Once LILO determines which operating system to start, it loads it into memory and hands control of the machine to that operating system.

Once the Stage 2 boot loader is in memory, LILO displays the initial Red Hat Linux screen with the different operating systems or kernels it has been configured to boot. If you only have Red Hat Linux installed and have not changed anything in LILO's configuration file, you will see only **linux** as an option. If you install SMP kernel support, you will see **linux-up** as an option. If you have set up LILO to boot other operating systems as well, this screen is your chance to select what operating system will boot. Use your arrow keys to highlight the operating system and press [Enter]

If you would like to have a command prompt to enter a command to LILO, press [Ctrl]-[X]. LILO displays a `LILO:` prompt on the screen and waits for input from the user.

2. For more on the system BIOS and the MBR, see Section 3.2.1.

4.8.2. LILO vs. GRUB

In general, LILO works similarly to GRUB except for three major differences:

- It has no interactive command interface.
- It stores information about the location of the kernel or other operating system it is to load on the MBR.
- It cannot read ext2 partitions.

The first point means the command prompt for LILO is not interactive and only allows one command with arguments.

The last two points mean that if you change LILO's configuration file or install a new kernel, you must rewrite the Stage 1 LILO boot loader to the MBR by issuing the `/sbin/lilo -v -v` command. This is more risky than GRUB's method, because a misconfigured MBR leaves the system unbootable. With GRUB, if the configuration file is erroneously configured, it will simply default to its command line interface.

Tip

If you upgrade the kernel using the **Red Hat Update Agent**, the MBR will be updated automatically. For more information on RHN, refer to the following URL, <https://rhn.redhat.com>

4.9. Options in `/etc/lilo.conf`

The `/sbin/lilo -v -v` command accesses the LILO configuration file, `/etc/lilo.conf`, to determine what to write to the MBR. If you are planning on using the `lilo` command, you need to know how to edit this file.

Warning

If you are planning to edit `/etc/lilo.conf`, be sure to make a backup copy of the file before making any changes. Also, be sure that you have a working boot floppy available so that you will be able to boot the system and make changes to the MBR if there is a problem. See the man pages for `mkbootdisk` for more information on creating a boot disk.

The file `/etc/lilo.conf` is used by `lilo` to determine which operating system or kernel to start, as well as to know where to install itself (for example, `/dev/hda` for the first MBR of the first IDE hard drive). A sample `/etc/lilo.conf` file looks like this (your `/etc/lilo.conf` may look a little different):

```
boot=/dev/hda
map=/boot/map
install=/boot/boot.b
prompt
timeout=50
message=/boot/message
lba32
default=linux

image=/boot/vmlinuz-2.4.0-0.43.6
```

```

label=linux
initrd=/boot/initrd-2.4.0-0.43.6.img
read-only
root=/dev/hda5

other=/dev/hda1
label=dos

```

This example shows a system configured to boot two operating systems: Red Hat Linux and DOS. Here is a deeper look at a few of the lines of this file:

- `boot=/dev/hda` tells LILO to install itself on the first hard disk on the first IDE controller.
- `map=/boot/map` locates the map file. In normal use, this should not be modified.
- `install=/boot/boot.b` tells LILO to install the specified file as the new boot sector. In normal use, this should not be altered. If the `install` line is missing, LILO will assume a default of `/boot/boot.b` as the file to be used.
- The existence of `prompt` tells LILO to show you whatever is referenced in the `message` line. While it is not recommended that you remove the `prompt` line, if you do remove it, you can still get a prompt by holding down the [Shift] key while your machine starts to boot.
- `timeout=50` sets the amount of time that LILO will wait for user input before proceeding with booting the default line entry. This is measured in tenths of a second, with 50 as the default.
- `message=/boot/message` refers to the screen that LILO displays to let you select the operating system or kernel to boot.
- `lba32` describes the hard disk geometry to LILO. Another common entry here is `linear`. You should not change this line unless you are very aware of what you are doing. Otherwise, you could put your system in an unbootable state.
- `default=linux` refers to the default operating system for LILO to boot from the options listed below this line. The name `linux` refers to the `label` line below in each of the boot options.
- `image=/boot/vmlinuz-2.4.0-0.43.6` specifies the linux kernel to boot with this particular boot option.
- `label=linux` names the operating system option in the LILO screen. In this case, it is also the name referred to by the `default` line.
- `initrd=/boot/initrd-2.4.0-0.43.6.img` refers to the *initial ram disk* image that is used at boot time to actually initialize and start the devices that makes booting the kernel possible. The initial ram disk is a collection of machine-specific drivers necessary to operate a SCSI card, hard drive, or any other device needed to load the kernel. You should never try to share initial ram disks between machines.
- `read-only` specifies that the root partition (see the `root` line below) is read-only and cannot be altered during the boot process.
- `root=/dev/hda5` tells LILO what disk partition to use as the root partition.

4.10. Changing Runlevels at Boot Time

Under Red Hat Linux, it is possible to change your default runlevel at boot time.

If you use LILO as your boot loader, access the `boot :` prompt by typing [Ctrl]-[X]. Then type:

```
linux number
```

In this command, replace *number* with either the number of the runlevel you wish to boot into (1 through 5), or the word **single**.

If you are using GRUB as your boot loader, follow these steps:

- In the graphical GRUB boot loader screen, select the **Red Hat Linux** boot label and press [e] to edit it.
- Arrow down to the kernel line and press [e] to edit it.
- At the prompt, type the number of the runlevel you wish to boot into (1 through 5), or the word **single** and press [Enter].
- You will be returned to the GRUB screen with the kernel information. Press the [b] key to boot the system.

For more information about runlevels, see Section 3.6.

4.11. Additional Resources

This chapter is only intended as an introduction to GRUB and LILO. Consult the following resources to discover more about how GRUB and LILO work.

4.11.1. Installed Documentation

- `/usr/share/doc/grub-0.92` — This directory contains good information about using and configuring GRUB.
- The GRUB info page, accessible by typing the `info grub` command, contains a tutorial, a user reference manual, a programmer reference manual, and an FAQ document about GRUB and its usage.
- `/usr/share/doc/lilo-21.4.4` — This directory contains a wealth of information about using and configuring LILO. In particular, the `doc` subdirectory contains a postscript file called `User_Guide.ps` that is highly informative.

4.11.2. Useful Websites

- <http://www.gnu.org/software/grub> — The home page of the GNU GRUB project. This site contains information concerning the state of GRUB development and a FAQ.
- <http://www.uruk.org/orig-grub> — The original GRUB documentation before the project was handed off to the Free Software Foundation for further development.
- <http://www.redhat.com/mirrors/LDP/HOWTO/mini/Multiboot-with-GRUB.html> — Investigates various uses for GRUB, including booting operating systems other than Linux.
- <http://www.linuxgazette.com/issue64/kohli.html> — An introductory article discussing the configuration of GRUB on a system from scratch, including an overview of GRUB command line options.
- <http://www.tldp.org/HOWTO/mini/LILO.html> — This mini-HOWTO discusses various uses for LILO, including booting operating systems other than Linux.

Users and Groups

Control of *users* and *groups* is a core element of Red Hat Linux system administration.

Users can be either people, meaning accounts tied to physical users, or logical users, meaning accounts which exist for specific applications to use. Both types of users have a unique *User ID (UID)* and *Group ID (GID)*.

Groups are logical expressions of organization. Groups tie users together, giving them permissions to read, write, or execute files.

When a file is created it is assigned a user and group. It is also assigned separate read, write, and execute permissions for the file's owner, group, and everyone else. The user and group of a particular file, as well as the access permissions on the file, can be changed by root or, in most cases, by the creator of the file.

Proper management of users and groups and effective management of file permissions, are among the most important tasks a system administrator undertakes in the course of his duties.

5.1. Tools for User and Group Creation

Managing users and groups can be a tedious task, but Red Hat Linux provides a few tools and conventions to make management easier for administrators.

You can use tools like `useradd` or `groupadd` to create new users and groups from the shell prompt. But an easier way to manage users and groups is through the graphical application, **User Manager**. For more information on **User Manager**, refer to the *Official Red Hat Linux Customization Guide*.

In Section 5.4 further discuss file permission concepts and will walk through command line steps for managing users.

5.2. Standard Users

In Table 5-1, you will find the standard users set up by the installation process in the `/etc/passwd` file. The Group ID (GID) in this table is the *primary group* for the user. See Section 5.3 for a listing of standard groups.

User	UID	GID	Home Directory	Shell
root	0	0	/root	/bin/bash
bin	1	1	/bin	/sbin/nologin
daemon	2	2	/sbin	/sbin/nologin
adm	3	4	/var/adm	/sbin/nologin
lp	4	7	/var/spool/lpd	/sbin/nologin
sync	5	0	/sbin	/bin/sync
shutdown	6	0	/sbin	/sbin/shutdown
halt	7	0	/sbin	/sbin/halt

User	UID	GID	Home Directory	Shell
mail	8	12	/var/spool/mail	/sbin/nologin
news	9	13	/var/spool/news	
uucp	10	14	/var/spool/uucp	/sbin/nologin
operator	11	0	/root	/sbin/nologin
games	12	100	/usr/games	/sbin/nologin
gopher	13	30	/usr/lib/gopher-data	/sbin/nologin
ftp	14	50	/var/ftp	/sbin/nologin
nobody	99	99	/	/sbin/nologin

ldap	55	
postdrop	90	
postfix	89	
privoxy	101	
pvm	24	

Table 5-2. Standard Groups

5.4. User Private Groups

Red Hat Linux uses a *user private group (UPG)* scheme, which makes UNIX groups easier to use. The UPG scheme does not add or change anything in the standard UNIX way of handling groups; it simply offers a new convention. Whenever you create a new user, by default, they have a unique group. The scheme works as follows:

User Private Group

Every user has a primary group; the user is the only member of that group.

`umask = 002`

Traditionally, on UNIX systems the `umask` is 022, which prevents other users *and other members of a user's primary group* from modifying a user's files. Since every user has their own private group in the UPG scheme, this "group protection" is not needed. A `umask` of 002 will prevent users from modifying other users' private files. The `umask` is set in `/etc/profile`.

setgid bit on Directories

If you set the `setgid` bit on a directory (with `chmod g+s directory`), files created in that directory will have their group set to the directory's group.

Many IT organizations like to create a group for each major project and then assign people to the group if they need to access that group's files. Using this traditional scheme, managing files has been difficult because when someone creates a file, it is associated with the primary group to which they belong. When a single person works on multiple projects, it is difficult to associate the right files with the right group. Using the UPG scheme, however, groups are automatically assigned to files created within a directory with the `setgid` bit set, which makes managing group projects that share a common directory very simple.

For example, say you have a big project called `devel`, with many people editing the `devel` files in a `devel` directory. Make a group called `devel`, `chgrp` the `devel` directory to `devel`, and add all of the `devel` users to the `devel` group.

You can add a user to a group using **User Manager** (see the *Official Red Hat Linux Customization Guide*), or if you prefer to use the command line, use the `/usr/sbin/groupadd groupname` command to create a group. The `/usr/bin/gpasswd -a loginname groupname` command will add a user `loginname` to a group. (See the `groupadd` and `gpasswd` man pages if you need more information on their options.) The `/etc/group` file contains the group information for your system.

If you created the `devel` group, added users to the `devel` group, changed the group for `devel` directory to the `devel` group, and set the `setgid` bit for the `devel` directory, all `devel` users will be able to edit the `devel` files and create new files in the `devel` directory. The files they create will always retain their `devel` group status, so other `devel` users will always be able to edit them.

If you have multiple projects like `devel` and users who are working on multiple projects, these users will never have to change their `umask` or group when they move from project to project. If set correctly, the `setgid` bit on each project's main directory "selects" the proper group for all files created in that directory.

Since each user's home directory is owned by the user and their private group, it is safe to set the `setgid` bit on the home directory. However, by default, files are created with the primary group of the user, so the `setgid` bit would be redundant.

5.4.1. User Private Group Rationale

Although the User Private Group (UPG) has existed in Red Hat Linux for quite some time, many people still have questions about it, such as why UPG is necessary. To illustrate its use, consider the following scenario.

You would like to have a group of people work on a set of files in the `/usr/lib/emacs/site-lisp/` directory. You trust a few people to modify the directory but certainly not everyone. So first create an `emacs` group:

```
/usr/sbin/groupadd emacs
```

In order to associate the contents of the directory with the `emacs` group, type:

```
chown -R root.emacs /usr/lib/emacs/site-lisp
```

Now, it is possible to add the proper users to the group with `gpasswd`:

```
/usr/bin/gpasswd -a <username> emacs
```

Allow the users to actually create files in the directory with the following command:

```
chmod 775 /usr/lib/emacs/site-lisp
```

When a user creates a new file, it is assigned the group of the user's default private group. To prevent this, perform the following command, which causes everything in the directory to be created with the `emacs` group:

```
chmod 2775 /usr/lib/emacs/site-lisp
```

If the new file needs to be mode 664 for another user in the `emacs` group to be able to edit it, make the default `umask` 002.

At this point, by making the default `umask` 002, you can easily set up groups that users can take advantage of without any extra work every time users write files to the group's common directory. Just create the group, add the users, and do the above `chown` and `chmod` on the group's directories.

5.5. Shadow Utilities

If you are in a multiuser environment and not using a networked authentication scheme such as Kerberos, you should consider using Shadow Utilities (also known as *shadow passwords*) for the enhanced protection offered for your system's authentication files. During the installation of Red Hat Linux, shadow password protection for your system is enabled by default, as are *MD5 passwords* (an alternative and arguably more secure method of encrypting passwords for storage on your system).

Shadow passwords offer a few distinct advantages over the previous standard of storing passwords on UNIX and Linux systems, including:

- Improved system security by moving the encrypted passwords (normally found in `/etc/passwd`) to `/etc/shadow` which is readable only by root
- Information concerning password aging (how long it has been since a password was last changed)
- Control over how long a password can remain unchanged before the user is required to change it
- The ability to use the `/etc/login.defs` file to enforce a security policy, especially concerning password aging

The `shadow-utils` package contains a number of utilities that support:

- Conversion from normal to shadow passwords and back (`pwconv`, `pwunconv`)
- Verification of the password, group, and associated shadow files (`pwck`, `grpck`)
- Industry-standard methods of adding, deleting and modifying user accounts (`useradd`, `usermod`, and `userdel`)
- Industry-standard methods of adding, deleting, and modifying user groups (`groupadd`, `groupmod`, and `groupdel`)
- Industry-standard method of administering the `/etc/group` file using `gpasswd`

There are some additional points of interest concerning these utilities:

- The utilities will work properly whether shadowing is enabled or not.
- The utilities have been slightly modified to support Red Hat's user private group scheme. For a description of the modifications, see the `useradd` man page. For more information on user private groups, turn to Section 5.4.
- The `adduser` script has been replaced with a symbolic link to `/usr/sbin/useradd`.
- The tools in the `shadow-utils` package are not Kerberos, NIS, hesiod, or LDAP enabled. New users will be local only. For more information on Kerberos and LDAP, see Chapter 10 and Chapter 18.

The X Window System

While the heart of Red Hat Linux is the kernel, for many users, the face of the operating system is the graphical environment provided by the *X Window System*, also called simply *X*.

This chapter is an introduction to the behind-the-scenes world of *XFree86*, the open-source implementation of *X* provided with Red Hat Linux.

6.1. The Power of X

Linux began as a powerful, server-based operating system, excelling at efficiently processing complicated programs requiring high CPU utilization and handling requests from hundreds or thousands of clients through network connections. However, because of its open nature and stability, Linux has quickly developed into a popular GUI-based operating system for workstations, both in the home or in the workplace.

In the UNIX™ world, windowing environments have existed for decades, predating many of the current mainstream operating systems. The X Window System is now the dominant graphical user interface (GUI) for UNIX-like operating systems.

To create this GUI for the user, *X* uses a client-server architecture. An *X server* process is started and *X client* processes can connect to it via a network or local loopback interface. The server process handles the communication with the hardware, such as the video card, monitor, keyboard, and mouse. The *X client* exists in the user-space, issuing requests to the *X server*.

On Red Hat Linux systems, the *XFree86* server fills the role of the *X server*. As a large scope open source software project, with hundreds of developers around the world, *XFree86* features rapid development, a wide degree of support for various hardware devices and architectures, and the ability to run on different operating systems and platforms.

Most Red Hat Linux desktop users are unaware of the *XFree86* server running on their system. They are much more concerned with the particular desktop environment in which they spend most of their time. The Red Hat Linux installation program does an excellent job of configuring your *XFree86* server during the installation process, ensuring that *X* performs optimally when first started.

The *X server* performs many difficult tasks using a wide array of hardware, requiring detailed configuration. If some aspect of your system changes, such as the monitor or video card, *XFree86* will need to be reconfigured. In addition, if you are troubleshooting a problem with *XFree86* that cannot be solved using a configuration utility, such as the **X Configuration Tool** (`redhat-config-xfree86`), you may need to access its configuration file directly.

X Configuration Tool is capable of configuring *XFree86* while the *X server* is active. To activate the configuration program from the command-line, type `redhat-config-xfree86`. To start **X Configuration Tool** while in an active *X* session, go to the **Main Menu Button** (on the Panel) => **System Tools** => **Display**. After using **X Configuration Tool** during an *X* session, you will need to log out of the current *X* session, then log back in for the changes to take effect.

6.2. XFree86

Red Hat Linux 8.0 uses XFree86 version 4.2 as the base X Window System, which includes the various necessary X libraries, fonts, utilities, documentation, and development tools.

Note

Red Hat no longer provides the older XFree86 version 3 server packages. Before upgrading to the latest version of Red Hat Linux be sure that your video card is compatible with XFree86 version 4 by checking the Red Hat Hardware Compatibility List located at this URL:<http://hardware.redhat.com/hcl/>.

The X server includes many cutting edge XFree86 technology enhancements such as hardware 3D acceleration support, the XRender extension for anti-aliased fonts, a modular driver based design, support for modern video hardware and input devices, and many other features.

The Red Hat Linux installation program installs the base components of XFree86. You may choose to install any optional XFree86 packages.

The X Window System resides primarily in two locations in the file system:

`/usr/X11R6/` directory

A directory containing X client binaries (the `bin` directory), assorted header files (the `include` directory), libraries (the `lib` directory), and manual pages (the `man` directory), and various other X documentation (the `/usr/X11R6/lib/X11/doc/` directory).

`/etc/X11/` directory

The `/etc/X11/` directory hierarchy contains all of the configuration files for the various components that make up the X Window System. This includes configuration files for the X server itself, the X font server (`xf86`), the X Display Manager (`xdm`), and many other base components. Display managers such as `gdm` and `kdm`, as well as various window managers, and other X tools also store their configuration in this hierarchy.

XFree86 version 4 server is a single binary executable — `/usr/X11R6/bin/XFree86`. This server dynamically loads various X server modules at runtime from the `/usr/X11R6/lib/modules/` directory including video drivers, font engine drivers, and other modules as needed. Some of these modules are automatically loaded by the server, whereas some are optional features that you must specify in the XFree86 server's configuration file, `/etc/X11/XF86Config`, before they can be used. The video drivers are located in the `/usr/X11R6/lib/modules/drivers/` directory. The DRI hardware accelerated 3D drivers are located in the `/usr/X11R6/lib/modules/dri/` directory.

6.2.1. XFree86 Server Configuration Files

The XFree86 server configuration files are stored in the `/etc/X11/` directory. The XFree86 version 4 server uses `/etc/X11/XF86Config`. When Red Hat Linux is installed, the configuration files for XFree86 are created using information gathered during the installation process.

While there is rarely a need to manually edit these files, it is useful to know about the various sections and optional parameters found in them.

Each section begins with a `Section "<section-name>"` line and ends with an `EndSection` line. Within each of the sections, you will find several lines containing an option name and at least one option value, occasionally seen in quotes. The following list explores the most useful sections of an XFree86 version 4 file and the roles of various popular settings.

Device

Specifies information about the video card used by the system. You must have at least one `Device` section in your configuration file. You may have multiple `Device` sections in the case of multiple video cards or multiple settings that can run a single card. The following options are required or widely used:

- `BusID` — Specifies the bus location of the video card. This option is only necessary for systems with multiple cards and must be set so that the `Device` section will use the proper settings for the correct card.
- `Driver` — Tells XFree86 which driver to load in order to use the video card.
- `Identifier` — Provides a unique name for this video card. Usually, this name is set to the exact name of the video card used in the `Device` section.
- `Screen` — An optional setting used when a video card has more than one *head*, or connector, to go out to a separate monitor. If you have multiple monitors connected to one video card, separate `Device` sections must exist for each of them with a different `Screen` value for each `Device` section. The value accepted by this option is a number starting at 0 and increasing by one for each head on the video card.
- `VideoRam` — The amount of RAM available on the video card in kilobytes. This setting is not normally necessary since the XFree86 server can usually probe the video card to autodetect the amount of video RAM. But since there are some video cards XFree86 cannot correctly autodetect, this option allows you to specify the amount of video RAM.

DRI

Direct Rendering Infrastructure (DRI) is an interface which primarily allows 3D software applications to take advantage of the 3D hardware acceleration capabilities on modern supported video hardware. In addition, DRI can improve 2D hardware acceleration performance when using drivers that have been enhanced to use the DRI for 2D operations. This section is ignored unless DRI is enabled in the `Module` section.

Since different video cards use DRI in different ways. Before changing any DRI values, read the `/usr/X11R6/lib/X11/doc/README.DRI` file for specific information about your particular video card.

Files

This section sets paths for services vital to the XFree86 server, such as the font path. Common options include:

- `FontPath` — Sets the locations where the XFree86 server can find fonts. Different fixed paths to directories holding font files can be placed here, separated by commas. By default, Red Hat Linux uses `xf86` as the font server and points `FontPath` to `unix/:7100`. This tells the XFree86 server to obtain font information by using UNIX-domain sockets for inter-process communication (IPC).

See Section 6.5 for more information concerning XFree86 and fonts.

- `ModulePath` — Allows you to set up multiple directories to use for storing modules loaded by the XFree86 server.
- `RgbPath` — Tells the XFree86 server where the RGB color database is located on the system. This database file defines all valid color names in XFree86 and ties them to specific RGB values.

InputDevice

Configures an input device such as a mouse or keyboard used to submit information into the system using the XFree86 server. Most systems have at least two `InputDevice` sections, keyboard and mouse. Each section includes these two lines:

- `Driver` — Tells XFree86 the name of the driver to load to use the device.
- `Identifier` — Sets the name of the device, usually the name of the device followed by a number, starting with 0 for the first device. For example, the first keyboard `InputDevice` would have an `Identifier Of Keyboard0`.

Most `InputDevice` sections contain lines assigning specific options to that device. Each of these lines start with `Option` and contain the name of the option in quotes, followed by the value to assign to that option. Mice usually receive options such as `Protocol`, such as `PS/2`, and `Device`, which designates the mouse to use for this section. The `InputDevice` section is well commented, allowing you to configure additional options for your particular devices by uncommenting certain lines.

Module

Tells the XFree86 server which modules from the `/usr/X11R6/lib/modules/` directory to load. Modules provide the XFree86 server with additional functionality.

Caution

You should not edit these values.

Monitor

Refers to the type of monitor used by the system. While one `Monitor` section is the minimum, there may be several `Monitor` sections, one for each monitor in use with the machine.

Warning

Be careful when manually editing values in the options of the `Monitor` section. Inappropriate values in this section could damage or destroy your monitor. Consult the documentation that came with your monitor for the safe operating parameters available.

The following options are usually configured during installation or when using **X Configuration Tool**:

- `HorizSync` — Tells XFree86 the range of horizontal sync frequencies compatible with the monitor in kHz. These values are used as a guide by the XFree86 server so that it will know whether to use a particular `Modeline` entry's values with this monitor.
- `Identifier` — Provides a unique name for this monitor, usually numbering each monitor starting at 0. The first monitor would be named `Monitor0`, the second `Monitor1`, and so on.
- `Modeline` — Used to specify the video modes used by the monitor at particular resolutions, with certain horizontal sync and vertical refresh resolutions. `Modeline` entries are usually preceded by a comment that explains what the mode line specifies.

If your configuration file does not include comments for the various mode lines, you can scan over the values (also called mode descriptions) to uncover what the mode line is attempting to do. See the `XF86Config` man page for detailed explanations of each mode description section.

- `ModelName` — An optional parameter that displays the model name of the monitor.
- `VendorName` — An optional parameter that displays the vendor that manufactured the monitor.

- `VertRefresh` — Lists the vertical refresh range frequencies supported by the monitor, in kHz. These values are used as a guide by the XFree86 server so that it will know whether to use a particular `Modeline` entry's values with this monitor.

Screen

Binds together a particular `Device` and `Monitor` that can be utilized as a pair and contain certain settings. You must have at least one `Screen` section in your configuration file. The following options are common:

- `DefaultDepth` — Tells the `Screen` section the default color depth to try in bits. 8 is the default, 16 provides thousands of colors, and 32 displays millions of colors.
- `Device` — Signifies the name of the `Device` section to use with this `Screen` section.
- `Identifier` — Identifies the `Screen` section so that it can be referred to by a `ServerLayout` section and be utilized.
- `Monitor` — Tells the name of the `Monitor` section to be used with this `Screen` section.

You may also have a `Display` subsection within the `Screen` section which tells the XFree86 server the color depth (`Depth`) and resolution (`Mode`) to try first when using this particular monitor and video card.

ServerFlags

Contains miscellaneous global XFree86 server settings. These settings may be overridden by options placed in the `ServerLayout` section. Among the most useful settings:

- `DontZap` — Prevents the use of the [Ctrl]-[Alt]-[Backspace] key combination to immediately terminate the XFree86 server.
- `DontZoom` — Prevents cycling through configured video resolutions using the [Ctrl]-[Alt]-[Keypad-Plus] and [Ctrl]-[Alt]-[Keypad-Minus] key combinations.

ServerLayout

Binds together a `Screen` section with the necessary `InputDevice` sections and various options to create a unified collection of preferences used by the XFree86 server as it starts. If you have more than one `ServerLayout` section, and the one to use is not specified on the command line when bringing up the XFree86 server, the first `ServerLayout` section in the configuration file is used.

The following options are used in a `ServerLayout` section:

- `Identifier` — A unique name used to describe this `ServerLayout` section.
- `InputDevice` — The names of any `InputDevice` sections to be used with the XFree86 server. Most users will only have two lines here, `Keyboard0` and `Mouse0`, the first keyboard and mouse configured for the system. The options `CoreKeyboard` and `CorePointer` refer to the fact that these are the preferred keyboard and mouse, respectively, to use with the XFree86 server.
- `Screen` — The name of the `Screen` section to use. The number to the left of the name of the `Screen` section refers to the particular screen number to use in a multi-head configuration. For standard single-head video cards, this value is 0. The numbers to the right give the X and Y absolute coordinates for the upper-left corner of the screen, by default 0 0.

Below is an example of a typical screen entry:

```
Screen      0 "Screen0" 0 0
```

For more information, refer to the `XF86Config` man page.

To review the current configuration of your XFree86 server, type the `xset -q` command. This provides you with information about the keyboard, pointer, screen saver, and font paths.

6.3. Desktop Environments and Window Managers

The configuration of an XFree86 server is useless until accessed by an X client that will use it to display a program using the hardware controlled by the X server. X clients are programs designed to take advantage of the X server's hardware, usually to provide interactivity with a user.

You do not have to run a complicated window manager in conjunction with a particular desktop environment to use X client applications. Assuming that you are not already in an X environment and do not have an `.xinitrc` file in your home directory, type the `xinit` command to start X with a basic terminal window (the default `xterm` application). You will see that this basic environment utilizes your keyboard, mouse, video card, and monitor with the XFree86 server, using the server's hardware preferences. Type `exit` at the `xterm` prompt to leave this basic X environment.

Of course, most computer users require more features and utility from their GUI. Developers have added layers of features to create highly developed and interactive environments that utilize the full power of the XFree86 server. These layers break into two fundamental groups based on their purpose.

6.3.1. Window Managers

Window managers are X client programs that control the way other X clients are positioned, resized, or moved. Window managers can also provide titlebars to windows, keyboard focus by keyboard or mouse, and user-specified key and mouse button bindings. Window managers work with a collection of different X clients, wrapping around the program, making it look a certain way and appear on the screen in a particular place.

Four window managers are included with Red Hat Linux 8.0:

- `twm` — The minimalist *Tab Window Manager*, which provides the most basic toolset of any of the window managers.
- `mwm` — The default window manager for the GNOME desktop environment, `mwm` stands for *Metacity Window Manager*. It is a simple and efficient window manager which supports custom themes.
- `sawfish` — This full featured window manager for was was the default until the release of Red Hat Linux 8.0. It can be used either with or without the GNOME desktop environment.
- `wmaker` — *WindowMaker* is a full-featured GNU window manager designed to emulate the look and feel of the NEXTSTEP environment.

These window managers can be run as individual X clients to gain a better sense of their differences. Type the `xinit <path-to-window-manager>` command, where `<path-to-window-manager>` is the location of the window manager binary file. The binary file can be found by typing `which <window-manager-name>` or by looking for the name of the window manager in a `bin` directory.

6.3.2. Desktop Environments

A *desktop environment* brings together assorted X clients that can be run together using similar methods, utilizing a common development environment.

Desktop environments are different from window managers, which only control the appearance and placement of X client windows. Desktop environments contain advanced features that allow X clients and other running processes to communicate with one another. This allows all applications written

to work in that environment to commonly integrate and be used in new ways, such as permitting drag-and-drop behavior with text.

GNOME is the default desktop environment for Red Hat Linux, using the GTK2 base widget toolkit and miscellaneous other widgets that extend the base functionality. KDE, another desktop environment, uses a different toolkit called Qt. GNOME and KDE both contain advanced productivity applications, such as word processors, spreadsheets, and control panel devices that allow you to have complete control of the look-and-feel of your user experience. Both environments can run standard X client applications, and most KDE applications can run in GNOME, if the Qt libraries are installed.

When you start X using the `startx` command, a pre-specified desktop environment is utilized. To change the default desktop environment used when X starts, open a terminal and type the `switchdesk` command. This brings up a graphical utility that allows you to select the desktop environment or window manager to use the next time X starts.

Desktop environments utilize window managers to provide the consistency in appearance between different applications. KDE contains its own window manager, called `kwm`, specifically for this functionality.

For information on the customization of the GNOME and KDE desktop environments, see the *Official Red Hat Linux Getting Started Guide*.

6.4. Runlevels

Most users run X from runlevels 3 or 5. Runlevel 3 places your system in multi-user mode with full networking capabilities. The machine will boot to a text-based login prompt with all necessary preconfigured services started. Most servers are run in runlevel 3, as X is not necessary to provide any services utilized by most users. Runlevel 5 is similar to 3, except that it automatically starts X and provides a graphical login screen. Many workstation users prefer this method, because it never forces them to see a command prompt.

The default runlevel used when your system boots can be found in the `/etc/inittab` file. If you have a line in that file that looks like `id:3:initdefault:`, then your system will boot to runlevel 3. If you have a line that looks like `id:5:initdefault:`, your system is set to boot into runlevel 5. As root, change the runlevel number in this file to set a different default. Save the file and restart your system to verify that it boots to the correct runlevel. More information on runlevels can be found in Section 3.6.

6.4.1. Runlevel 3: `startx`

When in runlevel 3, the preferred way to start an X session is to type the `startx` command. `startx`, a front-end to the `xinit` program, launches the XFree86 server and connects the X clients to it. Because you must already be logged into the system at runlevel 3 to be able to type commands, `startx` is only designed to bring up certain X clients, such as a desktop environment, in a particular manner. It does not provide any user authentication.

When `startx` begins, it looks for a `.xinitrc` file in the user's home directory to define the X clients to run. If it does not find that file present, it will run the system default `/etc/X11/xinit/xinitrc` script instead. The `startx` script then does the same thing with the `.xserverrc` file, looking for it in the user's home directory and then running the default `/etc/X11/xinit/xserverrc` script if it cannot be found. Since many different X clients exist, the `xinitrc` files are very important. The `xserverrc` script is less important. It only sets the X server to connect to the X clients. Since the default X server is already configured with the `/etc/X11/X` link, Red Hat Linux does not install a default `xserverrc`.

The default `xinitrc` script then looks for user-defined files and default system files, including `.Xresources`, `.Xmodmap`, and `.Xkbmap` in the user's home directory and `Xresources`, `Xmodmap`, and `Xkbmap` in the `/etc/X11/` directory. The `Xmodmap` and `Xkbmap` files, if they exist, are used by the

`xmodmap` utility to configure the keyboard. The `Xresources` files are read to assign specific preference values to particular applications.

After setting these options, the `xinitrc` script executes all scripts located in the `/etc/X11/xinit/xinitrc.d/` directory. One important script in this directory is `xinput`, which configures settings such as the default language to use and the desktop environment to start from (`/etc/sysconfig/desktop`).

Next, the `xinitrc` script tries to execute `.Xclients` in the user's home directory and turns to `/etc/X11/xinit/Xclients` if it cannot be found. The purpose of the `Xclients` file is to start the desktop environment or, possibly, just a basic window manager. The `.Xclients` script in the user's home directory starts the user-specified desktop environment or window manager in the `.Xclients-default` file. If `.Xclients` does not exist in the user's home directory, the standard `/etc/X11/init/Xclients` script attempts to start another desktop environment, trying GNOME first and then KDE. If a desktop environment cannot be found by this point, `Xclients` attempts the default window manager listed in the `.wm_style` file in the user's home directory. If this fails, it cycles through a predefined list of window managers.

The preferred X client applications should now have started by this point, along with the XFree86 server. If you need more details concerning starting X in runlevel 3, refer to the `startx` and `xinit` man pages and read through the scripts named above.

6.4.2. Runlevel 5: `prefdm`

Runlevel 5 uses a slightly different method to start X. When the system starts, no one is logged into the system by default. In order for a user to start a session, they must log in to the system. In runlevel 5, users authenticating themselves at the console use a *display manager*, a special X client that allows the user to submit their login name and password.

Depending on the desktop environments installed on your specific Red Hat Linux system, three different display managers are available to handle the user authentication. The `xdm` display manager is the original X authentication tool. `xdm` only allows you to log in and start an X session, nothing more. The `gdm` display manager, designed to work with the GNOME desktop environment, and `kdm` display manager, used with the KDE desktop environment, allow you to set the desktop environment, or *session*, you would like to use after authentication. Additionally, you can restart or halt the system from the login screen. The `gdm` display manager also allows you to configure the language you would like to use.

When the system enters runlevel 5, a line in the `/etc/inittab` file specifies that the `prefdm` script is executed in order to determine the preferred display manager to bring up for user authentication. The `prefdm` script uses the preferences stated in the `/etc/sysconfig/desktop` file to find the proper display manager. If no desktop environment is specified, `prefdm` cycles through the `gdm`, `kdm`, and `xdm` display managers to find one to use. Once one is found, `prefdm` launches it to handle the user login.

Each of the display managers look to the `/etc/X11/xdm/Xsetup_0` file to set up the login screen. Once the user logs into the system, the `/etc/X11/xdm/GiveConsole` script runs to assign ownership of the console to the user. Then, the `/etc/X11/xdm/Xsession` script runs to accomplish many of the tasks normally done by the `xinitrc` script when starting X in runlevel 3, including setting system and user resources, as well as running the scripts in the `/etc/X11/xinit/xinitrc.d/` directory.

The user can specify which desktop environment they want to utilize when they authenticate using the `gdm` or `kdm` display managers by selecting it from the **Session** menu. If the desktop environment is not specified in the display manager, the `/etc/X11/xdm/Xsession` script will check the `.xsession` and `.Xclients` files in the user's home directory to decide which desktop environment to load. As a last resort, the `/etc/X11/xinit/Xclients` file is used to select a desktop environment or window manager to use in the same way as runlevel 3.

When the user finishes an X session on the default display (:0) and logs out, the `/etc/X11/xdm/TakeConsole` script runs and reassigns ownership of the console to the root user. The original display manager, which continued running after the user logged in, takes control by spawning a new display manager. This restarts the XFree86 server, displays a new login window, and starts the entire process over again.

For more information about how display managers control user authentication, read the `xdm` man page.

6.5. Fonts

Red Hat Linux uses `xfs` (X Font Server) to provide fonts to the XFree86 server and the X client applications that connect to it. While it is possible to not use `xfs` and place the paths to font directories in your `XFree86Config` configuration file, `xfs` has several advantages:

- *It is easier to add and remove fonts, including editing the font path.* The *font path* is a collection of paths in the file system where font files are stored. The `xfs` service keeps the font path out of the XFree86 configuration files, making it easier to edit.
- *Fonts may be stored on one machine acting as a networked font server and can be shared among multiple X servers over the network.* A common set of fonts can be maintained in one place and easily shared between all users.
- *More types of fonts are supported.* `xfs` can handle TrueType, Type1, and bitmap fonts.

The XFree86 configuration files know whether to use `xfs` or hard coded font paths because of the `FontPath` setting in their `Files` sections. By default, the `FontPath` is set to `unix/:7100`. This tells the XFree86 server to connect to port 7100 using an inner-machine communication link. The `xfs` server listening on this port will respond with font information when queried by the XFree86 server.

The `xfs` service must be running when X is started. If it is not, you will be returned to a command prompt with an error similar to `failed to set default font path 'unix/:7100'`. Check to see if `xfs` is running using the `ps aux | grep xfs` command. By default, `xfs` is set to start in runlevels 2, 3, 4, and 5, covering all runlevels where you would run X. If `xfs` is not running on your system, you can start it as root using the `/sbin/service xfs start` command. Use the `/usr/sbin/ntsysv`, `serviceconf`, or `/sbin/chkconfig` utilities to force it to start at the correct runlevels. For more on configuring services for a particular runlevel, refer to the chapter titled *Controlling Access to Services* in the *Official Red Hat Linux Customization Guide*

6.5.1. `xfs` Configuration

The `/etc/rc.d/init.d/xfs` script starts the `xfs` server. Several options can be configured in the `/etc/X11/fs/config` file:

- `alternate-servers` — Sets a list of alternate font servers to be used if this font server is not available. A comma must separate every font server in the list.
- `catalogue` — An ordered list of font paths to use that contain the font files. A comma must follow every font path before a new font path can be started in the list.

You can use the string `:unscaled` immediately after the font path to make the unscaled fonts in that path load first. Then, you can specify the entire path again, so that other scaled fonts will also be loaded.

- `client-limit` — Sets the number of clients this font server will service before refusing to handle any more. The default is 10.

- `clone-self` — Decides if the font server will clone a new version of itself when the `client-limit` is hit. By default, this option is `on`. Set it to `off` to disable this feature.
- `default-point-size` — Sets the default point size for any font that does not specify this value. The value for this option is set in decipoints. The default of 120 corresponds to 12 point fonts.
- `default-resolutions` — Specifies a list of resolutions supported by the XFree86 server. Each resolution in the list must be separated by a comma.
- `deferglyphs` — Tells `xfs` whether to defer the loading of *glyphs*, which is an image used to visually represent a font. You can disable this feature (`none`), enable this feature for all fonts (`all`), or turn this this feature on only for 16-bit fonts (`16`), which are largely used with Asian languages.
- `error-file` — Allows you to specify the path and file name of a locations where `xfs` errors can be logged.
- `no-listen` — Tells `xfs` not to listen using a particular protocol. By default, this option is set to `tcp` to prevent `xfs` from listening on TCP ports, primarily for security reasons. If you plan on using `xfs` to serve fonts to networked workstations on a LAN, you need to remove the `tcp` from this line.
- `port` — Specifies the TCP port that `xfs` will listen on if `no-listen` does not exist or is commented out.
- `use-syslog` — Tells `xfs` to use the system error log if set to `on`.

6.5.2. Adding Fonts

When using `xfs`, adding fonts to your system is rather straightforward. Use the `chkfontpath --list` command to see the font paths currently configured on your system. To add new fonts in a new directory, follow these instructions as the root user:

1. Create a font directory, such as `/usr/share/fonts` and place the fonts inside that directory. Be sure to set the permissions correctly; it is only necessary that the files can be read, no other permissions are necessary.
2. Type the `chkfontpath --add <font-directory-path>` command, where the `<font-directory-path>` is the full path to the directory holding the fonts. This will add this font path to the `xfs` configuration file.

Note

You must have a `fonts.dir` file in your new font directory for the `chkfontpath` command to work correctly. The creation of the `fonts.dir` file, as well as any other files used by `xfs` with these fonts, is beyond the scope of this document.

Many font collections available for Linux include these files for you, it may not be necessary to create them by hand.

3. Restart `xfs` using the `/sbin/service xfs restart` command. You will also need to restart your X session.
4. Typing the `chkfontpath --list` command will show the new font path. Any fonts you added will be available for use.

The Red Hat Support website contains more information on this subject, see:

<http://www.redhat.com/support> for additional help documents.

6.6. Additional Resources

Much more can be said about the XFree86 server, the clients that connect to it, and the assorted desktop environments and window managers. Advanced users interested in tweaking their XFree86 configuration will find these additional sources of information useful.

6.6.1. Installed Documentation

- `/usr/X11R6/lib/X11/doc/README` — Briefly describes the XFree86 architecture and how to get additional information about the XFree86 project as a new user.
- `/usr/X11R6/lib/X11/doc/README.Config` — Explains the advanced configuration options open to XFree86 version 3 users.
- `/usr/X11R6/lib/X11/doc/RELNOTES` — For advanced users that want to read about the latest features available in XFree86.
- `man XF86Config` — Contains information about the XFree86 configuration files, including the meaning and syntax for the different sections within the files.
- `man XFree86` — The primary man page for all XFree86 information, details the difference between local and network X server connections, explores common environmental variables, lists command line options, and provides helpful administrative key combinations.
- `man Xserver` — Describes the X display server.

6.6.2. Useful Websites

- <http://www.xfree86.org> — Home page of the XFree86 project, which produces the XFree86 open source version of the X Window System. XFree86 is bundled with Red Hat Linux to control the necessary hardware and provide a GUI environment.
- <http://dri.sourceforge.net> — Home page of the DRI (Direct Rendering Infrastructure) project. The DRI is the core hardware 3D acceleration component of XFree86.
- <http://www.redhat.com/mirrors/LDP/HOWTO/XFree86-HOWTO> — A HOWTO document detailing the manual installation and custom configuration of XFree86.
- <http://www.gnome.org> — The home of the GNOME project.
- <http://www.kde.org> — The home of the KDE desktop environment.

6.6.3. Related Books

- *The Concise Guide to XFree86 for Linux* by Aron Hsiao; Que — Provides an expert's view of the operation of XFree86 on Linux systems.
- *The New XFree86* by Bill Ball; Prima Publishing — Discusses XFree86 and its relationship with the popular desktop environments, such as GNOME and KDE.
- *Beginning GTK+ and GNOME* by Peter Wright; Wrox Press, Inc. — Introduces programmers to the GNOME architecture, showing them how to get started with GTK+.
- *GTK+/GNOME Application Development* by Havoc Pennington; New Riders Publishing — An advanced look into the heart of GTK+ programming, focusing on sample code and a thorough look at the available APIs.

- *KDE 2.0 Development* by David Sweet and Matthias Ettrich; Sams Publishing — Instructs beginning and advanced developers in how to take advantage of the many environment guidelines required to built QT applications for KDE.

Security Reference

Pluggable Authentication Modules (PAM)

Programs which give privileges to users must properly authenticate each user. For instance, when you log into a system, you provide your username and password, and the log in process uses this username and password to verify your identity.

Pluggable Authentication Modules (PAM) allows the system administrator to set authentication policies for PAM-aware applications without having to recompile authentication programs. PAM does this by utilizing a pluggable, modular architecture. Which modules PAM calls for a particular application is determined by looking at that application's PAM configuration file in the `/etc/pam.d/` directory.

In most situations, you will never need to alter the default PAM configuration files for a PAM-aware application. Whenever you use RPM to install programs that require authentication, they automatically make the changes necessary to do normal password authentication using PAM. However, if you need to customize the PAM configuration file, you must understand the structure of this file (see Section 7.2 for more information).

7.1. Advantages of PAM

When used correctly, PAM provides the following advantages for a system administrator:

- It provides a common authentication scheme that can be used with a wide variety of applications.
- It allows great flexibility and control over authentication for both the system administrator and application developer.
- It allows application developers to develop their program without implementing a particular authentication scheme. Instead, they can focus purely on the details of their program.

7.2. PAM Configuration Files

The directory `/etc/pam.d/` contains the PAM configuration files for PAM-aware applications. In earlier versions of PAM, the file `/etc/pam.conf` was used, but this file is now deprecated. The `pam.conf` file is only read if the `/etc/pam.d/` directory does not exist.

Each PAM-aware application or *service* — as applications designed to be used by many users are commonly known — has its own file within the `/etc/pam.d/` directory.

These files have a specific layout containing calls to modules usually located in the `/lib/security/` directory. Additionally, each line within a PAM configuration file specifies a module type, a control flag, a path to the module, and, sometimes, module arguments.

7.2.1. PAM Service Names

Each PAM configuration file in the `/etc/pam.d/` directory is named after the service for which it controls access. It is up to the PAM-aware program to define its service name and install its PAM configuration file in the `pam.d` directory. For example, the `login` program defines its service name as `/etc/pam.d/login`.

In general, the service name is the name of the program used to *access* the service, not the program used to *provide* the service. This is why the service `wu-ftpd`, defines its service name as `/etc/pam.d/ftp`.

The next four sections will describe the basic format of PAM configuration files and how they use PAM modules to perform authentication for PAM-aware applications.

7.3. PAM Modules

There are four types of PAM modules used to control access to services. These types correlate to different aspects of the authorization process:

- `auth` — These modules are used to authenticate the user by, for example, asking for and checking a password. It can also set credentials, such as group membership or Kerberos tickets.
- `account` — These modules are used to make sure access is allowed. For example, it can check if the account is expired, or it can check if the user is allowed to log in at a particular time of day.
- `password` — These modules are used to set passwords.
- `session` — These modules are used after a user has been authenticated to manage the user's session. This module type can also perform additional tasks which are needed to allow access, like mounting a user's home directory or making his mailbox available.

Note

An individual module can address more than one of the above module types. For instance `pam_unix.so` has components which address all four module types.

In a PAM configuration file, the module type is the first aspect defined. For example a typical line in a configuration may look like this:

```
auth      required /lib/security/pam_unix.so
```

This instructs PAM to look at the `auth` component of the `pam_unix.so` module.

7.3.1. Stacking Modules

Modules can be *stacked*, or placed upon one another, so that multiple modules are used together for a particular purpose. Therefore the order in which the modules are listed is very important to the authentication process.

Stacking makes it very easy for an administrator to require several conditions to exist before allowing user authentication. For example, `rlogin` normally uses five stacked `auth` modules, as seen in its PAM configuration file:

```
auth      required /lib/security/pam_nologin.so
auth      required /lib/security/pam_securetty.so
auth      required /lib/security/pam_env.so
auth      sufficient /lib/security/pam_rhosts_auth.so
auth      required /lib/security/pam_stack.so service=system-auth
```

Before someone is allowed to use `rlogin`, PAM verifies that the `/etc/nologin` file does not exist, that they are not trying to log in remotely as a root user over an unencrypted network connection, and that any environmental variables can be loaded. Then, a successful `rhosts` authentication is performed before the connection is allowed. If `rhosts` authentication fails, then standard password authentication is performed.

7.3.2. Creating Modules

New PAM modules can be added at any time, and PAM-aware applications can then use them. For example, if you create a one-time-password creation method and write a PAM module to support it, PAM-aware programs can immediately use the new module and password method without being recompiled or otherwise modified. This is very beneficial because it lets you mix-and-match, as well as test, authentication methods for different programs without recompiling them.

Documentation on writing modules is included with the system in the `/usr/share/doc/pam-version-number/` directory.

7.4. PAM Module Control Flags

All PAM modules generate a success or failure result when checked. Control flags tell PAM what to do with the result. Since modules can be stacked in a particular order, control flags give you the ability to set the importance of a module in respect to the modules that follow it.

Again, consider the `rlogin` PAM configuration file:

```
auth      required      /lib/security/pam_nologin.so
auth      required      /lib/security/pam_securetty.so
auth      required      /lib/security/pam_env.so
auth      sufficient    /lib/security/pam_rhosts_auth.so
auth      required      /lib/security/pam_stack.so service=system-auth
```

Important

The order in which `required` modules are called is not critical. The `sufficient` and `requisite` control flags is what causes order to become important. See below for an explanation of each type of control flag.

After the module type is specified, the control flags decide how important the success or failure of that particular module should be in the overall goal of allowing access to the service.

Four types of control flags are defined by the PAM standard:

- `required` — the module must be successfully checked in order to allow authentication. If a `required` module check fails, the user is not notified until all other modules of the same module type have been checked.
- `requisite` — the module must be successfully checked in order for the authentication to be successful. However, if a `requisite` module check fails, the user is notified immediately with a message reflecting the first failed `required` *or* `requisite` module.
- `sufficient` — the module checks are ignored if it fails. But, if a `sufficient` flagged module is successfully checked and no `required` flagged modules above it have failed, then no other modules of this module type are checked and the user is authenticated.
- `optional` — the module checks are ignored if it fails. If the module check is successful, it does not play a role in the overall success or failure for that module type. The only time a module flagged as `optional` is necessary for successful authentication is when no other modules of that type have succeeded or failed. In this case, an `optional` module determines the overall PAM authentication for that module type.

A newer control flag syntax allowing for even more control is now available for PAM. Please see the PAM docs located in the `/usr/share/doc/pam-version-number/` directory for information on this new syntax.

7.5. PAM Module Paths

Module paths tell PAM where to find the pluggable module to be used with the module type specified. Usually, it is provided as the full path to the module, such as `/lib/security/pam_stack.so`. However, if the full path is not given (in other words, the path does not start with a `/`), then the module indicated is assumed to be in the `/lib/security/` directory — the default location for PAM modules.

7.6. PAM Module Arguments

PAM uses arguments to pass information to a pluggable module during authentication for a particular module type. These arguments allow the PAM configuration files for particular programs to use a common PAM module but in different ways.

For example, the `pam_userdb.so` module uses secrets stored in a Berkeley DB file to authenticate the user. Berkeley DB is an open source database system designed to be embedded in many applications to track information. The module takes a `db` argument, specifying the Berkeley DB filename to use, which can be different for different services.

So, the `pam_userdb.so` line in a PAM configuration file look like this:

```
auth    required /lib/security/pam_userdb.so db=path/to/file
```

Invalid arguments are ignored and do not otherwise affect the success or failure of the PAM module. When an invalid argument is passed, an error is usually written to `/var/log/messages` file. However, since the reporting method is controlled by the PAM module, the module must be written correctly to log the error to this file.

7.7. Sample PAM Configuration Files

Below is a sample PAM application configuration file:

```
##PAM-1.0
auth    required /lib/security/pam_securetty.so
auth    required /lib/security/pam_unix.so shadow nullok
auth    required /lib/security/pam_nologin.so
account required /lib/security/pam_unix.so
password required /lib/security/pam_cracklib.so retry=3
password required /lib/security/pam_unix.so shadow nullok use_authok
session required /lib/security/pam_unix.so
```

The first line is a comment as denoted by the `#` character — the comment symbol in PAM configuration files. Lines two through four stack three modules for login authentication.

```
auth    required /lib/security/pam_securetty.so
```

This line makes sure that *if* the user is trying to log in as root, the tty on which they are logging in is listed in the `/etc/securetty` file, *if* that file exists.

```
auth    required /lib/security/pam_unix.so nullok
```

This line causes the user to be asked for a password and then checks the password using the information stored in `/etc/passwd` and, if it exists, `/etc/shadow`. The `pam_unix.so` module automatically detects and utilizes shadow passwords, stored in `/etc/shadow`, to authenticate users. Please refer to the Section 5.5 for more information on shadow passwords.

The argument `nullok` instructs the `pam_unix.so` module to allow a blank password.

```
auth      required /lib/security/pam_nologin.so
```

This is the final authentication step. It checks to see if the file `/etc/nologin` exists. If `nologin` does exist and the user is not root, authentication fails.

Note

In this example, all three `auth` modules are checked, even if the first `auth` module fails. This prevents the user from knowing at what stage their authentication failed. Such knowledge in the hands of an attacker could allow them to more easily deduce how to crack the system.

```
account  required /lib/security/pam_unix.so
```

This line causes any necessary account verification to be done. For example, if shadow passwords have been enabled, the account component of the `pam_unix.so` module will check to see if the account has expired or if the user has not changed their password within the grace period allowed.

```
password required /lib/security/pam_cracklib.so retry=3
```

If a password has expired, the password component of the `pam_cracklib.so` module prompts for a new password. It then tests the newly created password to see whether it can easily be determined by a dictionary-based password cracking program. If it fails this test the first time, it gives the user two more chances to create a strong password, due to the `retry=3` argument.

```
password required /lib/security/pam_unix.so shadow nullok use_authtok
```

This line specifies that if the program changes the user's password, it should use the `password` component of the `pam_unix.so` module to do so. This will happen only if the `auth` portion of the `pam_unix.so` module has determined that the password needs to be changed — for example, if a shadow password has expired.

The argument `shadow` tells the module to create shadow passwords when updating a user's password.

The argument `nullok` instructs the module to allow the user to change their password *from* a blank password, otherwise a null password is treated as an account lock.

The final argument on this line, `use_authtok`, provides a good example of how one can stack PAM modules. This argument tells the module not to prompt the user for a new password. Instead it is to accept any password that passes through previous password module. This way all new passwords must pass the `pam_cracklib.so` test for secure passwords before being accepted.

```
session required /lib/security/pam_unix.so
```

The final line specifies that the session component of the `pam_unix.so` module will manage the session. This module logs the username and the service type to `/var/log/messages` at the the beginning and end of each session. It can be supplemented by stacking it with other session modules if you need more functionality.

The next sample configuration file will illustrate `auth` module stacking for the `rlogin` program — a program that allows users to log in remotely.

```

#%PAM-1.0
auth      required    /lib/security/pam_nologin.so
auth      required    /lib/security/pam_securetty.so
auth      required    /lib/security/pam_env.so
auth      sufficient  /lib/security/pam_rhosts_auth.so
auth      required    /lib/security/pam_stack.so service=system-auth

```

First, `pam_nologin.so` checks to see if `/etc/nologin` exists. If it does, no one can log in except for root.

```
auth      required    /lib/security/pam_securetty.so
```

The `pam_securetty.so` module then prevents root logins from occurring on insecure terminals. This effectively disallows all root `rlogin` attempts for security reasons.

Tip

If you need to log in as root, use OpenSSH instead. For more information on the SSH protocol, see Chapter 9.

```
auth      required    /lib/security/pam_env.so
```

This line loads the `pam_env.so` module, which sets the environmental variables specified in `/etc/security/pam_env.conf`.

```
auth      sufficient  /lib/security/pam_rhosts_auth.so
```

The `pam_rhosts_auth.so` modules then authenticates the user using `.rhosts` in the user's home directory. If this succeeds, PAM immediately authenticates the `rlogin` session. If `pam_rhosts_auth.so` fails to authenticate the user, this failed authentication attempt is ignored.

```
auth      required    /lib/security/pam_stack.so service=system-auth
```

If the `pam_rhosts_auth.so` module fails to authenticate the user, the `pam_stack.so` module performs normal password authentication.

The argument `service=system-auth` means the user must now pass through the PAM configuration for system authorization found in `/etc/pam.d/system-auth`.

Note

If you do not want to prompt for a password when the `securetty` check fails and determines that the user is trying to login as root remotely, you can change the `pam_securetty.so` module from `required` to `requisite`.

7.8. PAM and Device Ownership

Red Hat Linux allows the first privileged user to log in on the physical console of the machine the ability to manipulate devices and perform tasks normally reserved for root. This is done through a PAM module called `pam_console.so`.

7.8.1. Device Ownership

When a user logs into a machine under Red Hat Linux, the `pam_console.so` module is called by `login` or the graphical login programs, **gdm** and **kdm**. If this user is the first user to log in at the physical console — called the *console user* — the module grants ownership of a variety of devices normally owned by root. The console user owns these devices until the last local session for that user ends. Once the user has logged out, ownership of the devices reverts back to their default values.

The devices affected include, but are not limited to, sound cards, floppy drives, and CD-ROM drives.

This allows a local user to manipulate these devices without attaining root, thus simplifying common tasks for the console user.

In the file `/etc/security/console.perms`, you can edit the list of devices controlled by `pam_console.so`.

7.8.2. Application Access

The console user is also allowed access to any program with a file bearing the command name in the `/etc/security/console.apps/` directory. These files do not need to contain any data, but must have the exact name of the command to which they correspond.

One notable group of applications the console user has access to are three programs which shut off or reboot the system. These are:

- `/sbin/halt`
- `/sbin/reboot`
- `/sbin/poweroff`

Because these are PAM-aware applications, they call the `pam_console.so` as a requirement for use.

For more information see the man pages for `pam_console`, `console.perms`, and `console.apps`.

7.9. Additional Resources

Below is a list of information sources for using and configuring PAM on your system. In addition to these sources, you should read the PAM configuration files on your system to better understand how they are structured.

7.9.1. Installed Documentation

- `pam` man page — Good introductory information on PAM, including the structure and purpose of the PAM configuration files.
- `/usr/share/doc/pam-version-number` — Contains a *System Administrators' Guide*, a *Module Writers' Manual*, and an *Application Developers' Manual*. Also contains a copy of the PAM standard, DCE-RFC 86.0.

7.9.2. Useful Websites

- <http://www.kernel.org/pub/linux/libs/pam> — The primary distribution website for the Linux-PAM project, containing information on various PAM modules, a FAQ, and additional PAM documentation.

TCP Wrappers and `xinetd`

Controlling access to network services can be a challenge. Firewalls are useful for controlling access in and out of a particular network, but they can be difficult to configure. TCP wrappers and `xinetd` control access to services by hostname and IP addresses. In addition, these tools also include logging and utilization management capabilities that are easy to configure.

8.1. What Are TCP Wrappers?

TCP wrappers is installed by default with a server-class installation of Red Hat Linux 8.0, and provides access control to a variety of services. Most modern network services, such as SSH, Telnet, and FTP, make use of *TCP wrappers*, a program that is designed to stand guard between an incoming request and the requested service.

The idea behind TCP wrappers is that client requests to server applications are "wrapped" by an authenticating service, allowing a greater degree of access control and logging for anyone attempting to use the service.

The functionality behind TCP wrappers is provided by `libwrap.a`, a library that network services, such as `xinetd`, `sshd`, and `portmap`, are compiled against. Additional network services, even networking programs you may write, can be compiled against `libwrap.a` to provide this functionality. Red Hat Linux bundles the necessary TCP wrapper programs and library in the `tcp_wrappers-<version>` RPM file.

8.1.1. TCP Wrapper Advantages

When a user attempts to gain client access to a network service that is using TCP wrappers, a small wrapper program reports the name of the service requested and the client's host information. The wrapper program does not directly send any information back to the client, and after the access control directives are satisfied, the wrapper is unloaded and frees up its resources. The client and the server can then resume actions without further wrapper intervention.

TCP wrappers provide two basic advantages over other network service control techniques:

- *The connecting client is unaware that TCP wrappers are in use.* — Legitimate users will not notice anything different, and attackers never receive any additional information about why their attempted connections have failed.
- *TCP wrappers operate separately from the applications the wrapper program protects.* — This allows many server applications to share a common set of configuration files for simpler management.

8.2. Host-Based Access Control Lists

Host-based access for services that use TCP wrappers is controlled by two files: `/etc/hosts.allow` and `/etc/hosts.deny`. These files use a simple format to control access to services on a server.

If no rules are specified in either `hosts.allow` or `hosts.deny`, then the default rule is to allow anyone to access to the services.

Order is important since rules in `hosts.allow` take precedence over rules specified in `hosts.deny`. Even if a rule specifically denying all access to a particular service is defined in `hosts.deny`, `hosts`

specifically given access to the service in `hosts.allow` are allowed to access the service. In addition, all rules in each file take effect from the top down.

Any changes to these files take effect immediately, so restarting services is not required.

8.2.1. Formatting Rules

All access control rules are placed on lines within `hosts.allow` and `hosts.deny`, and any blank lines or lines that start with the comment character (`#`) are ignored. Each rule needs to be on its own line.

The rules must be formatted in the following manner:

```
<daemon_list>: <client_list>[: spawn <shell_command> ]
```

Each of these options refer to a different part of the rule:

- `daemon_list` — A collection of one or more process names or special wildcards, separated by whitespace.
- `client_list` — One or more hostnames, host addresses, patterns, or wildcards, separated by whitespace, to use when a particular process name matches a requested service.
- `shell_command` — An optional component that specifies something to be done in the event a rule is utilized.

Patterns are particularly helpful when specifying groups of clients that may or may not access a certain service. By placing a "." character at the beginning of a string, all hosts that share the end of that string are applied to that rule. So, `.domain.com` would catch both `system1.domain.com` and `system2.domain.com`. The "." character at the end of a string has the same effect, except going the other direction. This is primarily used for IP addresses, as a rule pertaining to `192.168.0.` would apply to the entire class C block of IP addresses. Netmask expressions can also be used as a pattern to control access to a particular group of IP addresses. You can even use asterisks (*) or question marks (?) to select entire groups of hostnames or IP addresses, so long as you do not use them in the same string as the other types of patterns.

If a list of hostnames with access a service is too long or is difficult to control within `host.allow` or `hosts.deny`, you can also specify the full path to a file (such as `/etc/telnet.hosts.deny`). This file contains hostnames, host addresses, or patterns, separated by whitespace, that you want to allow or deny access to that service. This method also works well to share access control lists between various services, as changes would only need to be made in one file per service.

The following wildcards may be used in the access control rules instead of using specific hosts or groups of hosts:

- `ALL` — Matches every client with a service. To allow a client access to all services, use the `ALL` in the daemons section.
- `LOCAL` — Matches any host that does not contain a "." character.
- `KNOWN` — Matches any host where the hostname and host address are known or where the user is known.
- `UNKNOWN` — Matches any host where the hostname or host address are unknown or where the user is unknown.
- `PARANOID` — Matches any host where the hostname does not match the host address.

**Caution**

The `KNOWN`, `UNKNOWN`, and `PARANOID` wildcards should be used very carefully, as a disruption in name resolution may make prevent legitimate users from gaining access to a service.

The access control language also contains a powerful operator, `EXCEPT`, which allows separate lists to be combined within the same rule line. When `EXCEPT` is used between two lists, the first list applies unless an entry from the second list matches an entity covered by the first list. `EXCEPT` can be used with daemon or client lists. Consider the following `hosts.allow` example:

```
# all domain.com hosts are allowed to connect
# to all services except cracker.domain.com
ALL: .domain.com EXCEPT cracker.domain.com

# 123.123.123.* addresses can use all services except FTP
ALL EXCEPT in.ftpd: 123.123.123.
```

**Note**

Organizationally, it usually makes more sense to use `EXCEPT` operators sparingly, choosing instead to place the exceptions to the rule in the other access control file. This allows all administrators to quickly scan the appropriate files to see what hosts should be allowed or denied access to which services, without having to sort through the various `EXCEPT` operators.

The best way to manage access control with `hosts.allow` and `hosts.deny` is to use the two files together to achieve the desired results.

Users that wish to prevent any hosts other than specific ones from accessing services usually place `ALL: ALL` in `hosts.deny`. Then, they place lines in `hosts.allow`, such as:

```
in.telnetd: 10.0.1.24
in.ftpd: 10.0.1. EXCEPT 10.0.1.1
```

Alternatively, if you wish to allow anyone to use network services except for specific hosts, leave `hosts.allow` blank and add any necessary restrictions to `hosts.deny` such as:

```
in.fingerd: 192.168.0.2
```

**Warning**

Be very careful about using hostnames and domain names in both access control files, especially `hosts.deny`. Various tricks could be used by an attacker to circumvent rules specifying a hostname or domain name. In addition, if your system selectively allows access based on hostname and domain name information, any disruption in DNS service would prevent even authorized users from using network services.

Using IP addresses whenever possible can prevent many problems when constructing access control rules, especially those that deny access.

Beyond simply allowing or denying access to services for certain hosts, the TCP wrappers also supports the use of shell commands. These shell commands are most commonly used with deny rules to set up booby traps, which usually trigger actions that log information about failed attempts to a

special file or email an administrator. Below is an example of a booby trap in the `hosts.deny` file which will write a log line containing the date and client information every time a host from the IP range 10.0.1.0 to 10.0.1.255 attempts to connect via Telnet:

```
in.telnetd: 10.0.1.: spawn (/bin/echo `date` %c >> /var/log/telnet.log) &
```

Another feature of using shell commands is support for *expansions*. Expansions provide the command with information about the client, server, and process involved. Below is a list of supported expansions:

- `%a` — The client's IP address.
- `%A` — The server's IP address.
- `%c` — Supplies a variety of client information, such as the username and hostname, or the username and IP address.
- `%d` — The daemon process name.
- `%h` — The client's hostname (or IP address, if the hostname is unavailable).
- `%H` — The server's hostname (or IP address, if the hostname is unavailable).
- `%n` — The client's hostname. If unavailable, `unknown` is printed. If the client's hostname and host address do not match, `paranoid` is printed.
- `%N` — The server's hostname. If unavailable, `unknown` is printed. If the server's hostname and host address do not match, `paranoid` is printed.
- `%p` — The daemon process ID.
- `%s` — Various types of server information, such as the daemon process and the host or IP address of the server.
- `%u` — The client's username. If unavailable, `unknown` is printed.

For a full explanation of available shell commands, as well as some additional access control examples, review see the man page for `hosts_access`.

Note

Special attention must be given to `portmap` when host access control lists. Only IP addresses or the `ALL` option should be used when specifying hosts to allow or deny, as host names are not supported. In addition, changes to the host access control lists that concern `portmap` may not take affect immediately.

As widely used services, such as NIS and NFS, depend on `portmap` to operate, be aware of these limitations before depending on `hosts.allow` and `hosts.deny` to control access.

8.3. Access Control Using `xinetd`

The benefits offered by TCP wrappers are enhanced when the `libwrap.a` library is used in conjunction with `xinetd`, a *super-daemon* that provides additional access, logging, binding, redirection and resource utilization control.

Red Hat Linux configures a variety of popular network services to be used with `xinetd`, including FTP, IMAP, POP, and Telnet. When any of these services are accessed via their port numbers in `/etc/services`, the `xinetd` daemon handles the request. Before bringing up the requested network service, `xinetd` ensures that the client host information meets the access control rules, the number of

instances of this service is under a particular threshold, and any other rules specified for that service or all `xinetd` services are followed. Once the target service is brought up for the connecting client, `xinetd` goes back to sleep, waiting for additional requests for the services it manages.

8.3.1. `xinetd` Configuration Files

The `xinetd` service is controlled by the `/etc/xinetd.conf` file, as well as the various service-specific files in the `/etc/xinetd.d/` directory.

8.3.1.1. `/etc/xinetd.conf`

The `xinetd.conf` file is the parent of all `xinetd`-controlled service configuration files, as the service-specific files are also parsed every time `xinetd` starts. By default, `xinetd.conf` contains some basic configuration settings that apply to every service. Below is an example of a typical `xinetd.conf`:

```
defaults
{
    instances             = 60
    log_type              = SYSLOG authpriv
    log_on_success        = HOST PID
    log_on_failure        = HOST
    cps                   = 25 30
}

includedir /etc/xinetd.d
```

These lines control various aspects of `xinetd`:

- `instances` — Sets the maximum number of requests a particular service can handle at once.
- `log_type` — Tells `xinetd` to use the `authpriv` log, specified in `/etc/syslog.conf` and set to `/var/log/secure` by default, rather than using another specific file. Using `FILE /var/log/xinetdlog` here instead would move `xinetd` logging to a separate `/var/log/xinetdlog` file.
- `log_on_success` — Lets `xinetd` know what to log if the connection is successful. By default, the remote host's IP address and the process ID of server processing the request are recorded.
- `log_on_failure` — Tells `xinetd` what to log if the connection fails or is not allowed.
- `cps` — Tells `xinetd` to allow no more than 25 connections per second to a given service. If this limit is reached, the service is retired for 30 seconds.

Note

Both the `log_on_success` and `log_on_failure` settings in `/etc/xinetd.conf` are often modified by each service, meaning that successful and failed connections will usually log more information than is indicated in `/etc/xinetd.conf`.

Various logging options are available in `/etc/xinetd.conf` and the service-specific `xinetd` configuration files:

- `ATTEMPT` — Logs the fact that a failed attempt was made. (`log_on_failure`)
- `DURATION` — Logs the length of time the service is used by a remote system. (`log_on_success`)

- `EXIT` — Logs the exit status or termination signal of the service. (`log_on_success`)
- `HOST` — Logs the remote host's IP address. (`log_on_failure` and `log_on_success`)
- `PID` — Logs the process ID of the server receiving the request. (`log_on_success`)
- `RECORD` — Records information about the remote system in the case the service cannot be started. Only particular services, such as `login` and `finger`, may use this option. (`log_on_failure`)
- `USERID` — Logs the remote user using the method defined in RFC 1413 for all multi-threaded stream services. (`log_on_failure` and `log_on_success`)

Other options for `/etc/xinetd.conf` are available, such as `per_source`, which limits the maximum number of connections from a particular IP address to a specific service. See the man page for `xinetd` for more information.

8.3.1.2. Files in the `/etc/xinetd.d/` Directory

The files in the `/etc/xinetd.d/` directory are read every time `xinetd` starts, due to the `includedir /etc/xinetd.d/` statement at the bottom of `/etc/xinetd.conf`. These files, with names such as `finger`, `ipop3`, and `rlogin`, correlate to the services controlled by `xinetd`.

The files in `/etc/xinetd.d/` use the same conventions as `/etc/xinetd.conf`. The primary reason they are stored in separate configuration files is to make it easier to add and remove a service from `xinetd` without affecting other services.

To get an idea of how these files are structured, consider the `wu-ftp` file:

```
service ftp
{
    socket_type          = stream
    wait                = no
    user                 = root
    server               = /usr/sbin/in.ftpd
    server_args          = -l -a
    log_on_success       += DURATION USERID
    log_on_failure       += USERID
    nice                 = 10
    disable              = yes
}
```

The first line defines the service's name. The lines within the brackets contain settings that define how this service is supposed to be started and used. The `wu-ftp` file states that the FTP service uses a `stream` socket type (rather than `dgram`), the binary executable file to use, the arguments to pass to the binary, the information to log in addition to the `/etc/xinetd.conf` settings, the priority with which to run the service, and more.

The use of `xinetd` with a service also can serve as a basic level of protection from a Denial of Service (DoS) attack. The `max_load` option takes a floating point value to set a CPU usage threshold when no more connections for a particular service will be accepted, preventing certain services from overwhelming the system. The `cps` option accepts an integer value to set a rate limit on the number of connections available per second. Configuring this value to something low, such as 3, will help prevent attackers from being able to flood your system with too many simultaneous requests for a particular service.

8.3.1.3. Access Control within `xinetd`

Users of `xinetd` services can choose to use the TCP wrapper host access control files (`/etc/hosts.allow` and `/etc/hosts.deny`), provide access control via the `xinetd` configuration files, or a mixture of both. Information concerning the use of TCP wrapper host access control files can be found in Section 8.2. This section will discuss using `xinetd` to control access to services.

Note

Unlike TCP wrapper host access control files, any changes to `xinetd` configuration files require a restart of the `xinetd` service to go into affect.

The `xinetd` host access control available through its various configuration files is different from the method used by TCP wrappers. While TCP wrappers places all of the access configuration within two files, `/etc/hosts.allow` and `/etc/hosts.deny`, each service's file in `/etc/xinetd.d` can contain access control rules based on the hosts that will be allowed to use that service.

The following options are supported in the `xinetd` files to control host access:

- `only_from` — Allows the hosts specified to use the service.
- `no_access` — Blocks these hosts from using this service.
- `access_times` — Specifies the time range when a particular service may be used. The time range must be stated in a `HH:MM-HH:MM` format using 24-hour notation.

The `only_from` and `no_access` options can use a list of IP addresses or host names, or can specify an entire network. Like TCP wrappers, combining `xinetd` access control with the proper logging configuration for that service, you can not only block the request but also record every attempt to access it.

For example, the following `/etc/xinetd.d/telnet` file can be used to block `telnet` access to a system by a particular network group and restrict the overall time range that even legitimate users can log in:

```
service telnet
{
    disable           = no
    flags             = REUSE
    socket_type       = stream
    wait              = no
    user              = root
    server             = /usr/sbin/in.telnetd
    log_on_failure    += USERID
    no_access         = 10.0.1.0/24
    log_on_success    += PID HOST EXIT
    access_times      = 09:45-16:15
}
```

In this example, when any system from the `10.0.1.0/24` subnet, such as `10.0.1.2`, tries to `telnet` into the server, they will receive a message stating `Connection closed by foreign host.` In addition, their login attempt is logged in `/var/log/secure`:

```
May 15 17:35:47 boo xinetd[16188]: START: telnet pid=16191 from=10.0.1.2
May 15 17:38:49 boo xinetd[16252]: START: telnet pid=16256 from=10.0.1.2
May 15 17:38:49 boo xinetd[16256]: FAIL: telnet address from=10.0.1.2
May 15 17:38:49 boo xinetd[16252]: EXIT: telnet status=0 pid=16256
```

8.3.1.4. Binding and Port Redirection

The service configuration files for `xinetd` also support binding the service to an IP address and redirecting incoming requests for that service to another IP address, hostname, or port.

Binding is controlled with the `bind` option in the service configuration files and links the service to one IP address on the system. When used, the `bind` option only allows requests for the proper IP address to access the service. Each service can be bound to different network interfaces based on your needs. This is particularly useful for systems with multiple network adapters or using multiple IP addresses. For instance, you can configure `telnet` to listen only on the interface connected to a private network and not to the interface connected with the Internet.

The `redirect` option accepts an IP address or hostname followed by a port number. It tells the service to redirect any requests for this service to the specified host and port number. This feature can be used to point to another port number on the same system, redirect the request to different IP address on the same machine, shift the request to a totally different system and port number, or any combination of these options. In this way, a user connecting to certain service on a system may be rerouted to another system with no disruption.

The `xinetd` daemon is able to accomplish this redirection by spawning a process that stays alive for the duration of the connection between the requesting client machine and the host actually providing the service, transferring data between the two systems.

The real strength of the `bind` and `redirect` options can be seen when they are used together. By binding a service to a particular IP address on a system and then redirecting requests for this service to a second machine that only the first machine can see, you can use an internal system to provide services for a totally different network. Alternatively, these options can be used to limit the exposure of a particular service on a multi-homed machine to a known IP address, as well as redirect any requests for that service to another machine specially configured for that purpose.

For example, consider a system that is used as a firewall with this setting for its `telnet` service:

```
service telnet
{
    socket_type = stream
    wait       = no
    server     = /usr/sbin/in.telnetd
    log_on_success += DURATION USERID
    log_on_failure += USERID
    bind       = 123.123.123.123
    redirect   = 10.0.1.13 21 23
}
```

The `bind` and `redirect` options in this file will ensure that the `telnet` service on the machine is bound to the external IP address (123.123.123.123), the one facing the Internet. In addition, any requests for `telnet` service sent to 123.123.123.123 will be redirected via a second network adapter to an internal IP address (10.0.1.13) that only the firewall and internal systems can access. The firewall will then send the communication between the two systems, and the connecting system will think it is connected to 123.123.123.123 when it is actually connected to a different machine.

This feature is particularly useful for users with broadband connections and only one fixed IP address. When using Network Address Translation (NAT), the systems behind the gateway machine, which are using internal-only IP addresses, are not available from outside the gateway system. However, when certain services controlled by `xinetd` are configured with the `bind` and `redirect` options, the gateway machine can act as a type of proxy between outside systems and a particular internal machine configured to provide the service. In addition, the various `xinetd` access control and logging options are also available for additional protection, such as limiting the number of simultaneous connections for the redirected service.

8.4. Additional Resources

Additional information concerning TCP wrappers and `xinetd` is available on system documentation and on the Web.

8.4.1. Installed Documentation

The bundled documentation on your system is a good place to start looking for additional TCP Wrappers, `xinetd`, and access control configuration options.

- `/usr/share/doc/tcp_wrappers-<version>` — Contains a `README` file that discusses how TCP wrappers work and the various hostname and host address spoofing risks that exist.
- `/usr/share/doc/xinetd-<version>` — Includes a `README` file that discusses aspects of access control and a `sample.conf` file with various ideas for modifying `/etc/xinetd.d` service configurations.
- For detailed information concerning the creation of TCP wrapper access control rules, read the `hosts_access(5)` and `hosts_options(5)` man pages.
- The `xinetd(8)` and `xinetd.conf(5)` man pages contain additional information for creating `xinetd` configuration files and a description of how `xinetd` works.

8.4.2. Useful Websites

- <http://www.xinetd.org> — The home of `xinetd`, containing sample configuration files, a full listing of features, and an informative FAQ.
- <http://www.macsecurity.org/resources/xinetd/tutorial.shtml> — A thorough tutorial that discusses many different ways to tweak default `xinetd` configuration files to meet specific security goals.

SSH Protocol

SSH™ allows users to log into host systems remotely. Unlike `rlogin` or `telnet` SSH encrypts the login session, making it impossible for intruders to collect clear-text passwords.

SSH is designed to replace older, less secure terminal applications used to log into remote systems, such as **telnet** or **rsh**. A related program called `scp` replaces older programs designed to copy files between hosts, such as **ftp** or **rcp**. Because these older applications do not encrypt passwords between the client and the server, you should avoid them whenever possible. Using secure methods to remotely log into other systems will decrease the security risks for both your system and the system you are logging into.

9.1. Features of SSH

SSH (or *Secure SHell*) is a protocol for creating a secure connection between two systems using a client server architecture. Under the SSH protocol, the client machine initiates all connections to a server.

The SSH protocol provides the following safeguards:

- After an initial connection, the client verifies it is connecting to the same server during subsequent sessions.
- The client transmits its authentication information to the server, such as a username and password, in an encrypted format.
- All data sent and received during the connection is transferred using strong, 128 bit encryption, making intercepted transmissions extremely difficult to decrypt and read.
- The client has the ability to use X11¹ applications launched from the shell prompt. This technique, called *X11 forwarding*, provides a secure means to use graphical applications over a network.

Because the SSH protocol encrypts everything it sends and receives, it can be used to secure otherwise insecure protocols. Using a technique called *port forwarding*, an SSH server can become a conduit to secure insecure protocols, like POP, increasing overall system and data security.

Red Hat Linux 8.0 includes the general OpenSSH package (`openssh`), the OpenSSH server (`openssh-server`) and client (`openssh-clients`) packages. Please see the chapter titled *OpenSSH* in the *Official Red Hat Linux Customization Guide* for instructions on installing and deploying OpenSSH. Also note that the OpenSSH packages require the OpenSSL package (`openssl`). OpenSSL installs several important cryptographic libraries that help OpenSSH provide encrypted communications.

A large number of client and server programs can use the SSH protocol. Several different SSH client versions are available for almost every major operating system in use today. Even if the users connecting to your system are not running Red Hat Linux, they can still find and use an SSH client native for their operating system.

1. X11 refers to the X11R6 windowing display system, traditionally referred to as X. Red Hat Linux includes **XFree86**, a widely used, open source X Window System, which is based on X11R6.

9.1.1. Why Use SSH?

Nefarious computer users have a variety of tools at their disposal to disrupt, intercept, and re-route network traffic in an effort to gain access to your system. In general terms, these threats can be categorized as follows:

- *Interception of communication between two systems* — In this scenario, the attacker can be somewhere on the network between the communicating entities, copying any information passed between them. The attacker may intercept and keep the information or alter the information and send it on to the intended recipient.

This can be attack can be mounted through the use of a packet sniffer — a common network utility.

- *Impersonation of a particular host* — Using this strategy, an attacker's system is configured to pose as the intended recipient of a transmission. If this strategy works, the user's system will remain unaware it is communicating with the wrong host.

This can be attack can be mounted through techniques known as DNS poisoning² or IP spoofing³.

Both techniques intercept potentially sensitive information, and if the interception is for hostile reasons, the results can be disastrous.

If SSH is used for remote shell login and file copying, these security threats can be greatly diminished. This is because the SSH client and server use digital signatures to verify their identity. Additionally, all communication between the client and server systems is encrypted. Attempts to spoof the identity of either side of a communication will not work, since each packet is encrypted using a key known only by the local and remote systems.

9.2. Event Sequence of an SSH Connection

The following series of events help protect the integrity of SSH communication between two hosts.

First, a secure transport layer is created so that the client knows it is communicating with the correct server. Then, the communication is encrypted between the client and server using a symmetric cipher.

With an encrypted connection to the server in place, the client safely authenticates itself to the server without sending information in plain text.

Finally, with the client authenticated to the server, several different services can be safely and securely used through the connection, such as an interactive shell session, X11 applications, and tunneled TCP/IP ports.

9.3. Layers of SSH Security

The SSH protocol allows any client and server programs built to the protocol's specifications to communicate securely and to be used interchangeably.

Two varieties of SSH currently exist. SSH version 1 contains several patented encryption algorithms (however, several of these patents have expired) and a security hole that potentially allows for data to be inserted into the data stream. The OpenSSH suite under Red Hat Linux 8.0 uses SSH version 2.0 by default, although it also supports version 1. It is recommended that you use SSH version 2-compatible servers and clients whenever possible.

2. DNS poisoning occurs when an intruder cracks a DNS server, pointing client systems to a maliciously duplicated host.

3. IP spoofing occurs when an intruder sends network packets which falsely appear to be from a trusted host on the network.

Both SSH protocol versions 1 and 2 add layers of security with each of these layers providing its own type of protection.

9.3.1. Transport Layer

The primary role of the transport layer is to facilitate safe and secure communication between the two hosts at the time of and after authentication. Usually running over TCP/IP, the transport layer accomplishes this by handling the encryption and decryption of data and providing integrity protection of data packets as they are sent and received. In addition, the transport layer provides compression, speeding the transfer of information.

Once an SSH client contacts a server, key information is exchanged so that the two systems can correctly construct the transport layer. The following steps occur during this exchange:

- Key exchange
- The public key algorithm to be used
- The symmetric encryption algorithm to be used
- The message authentication algorithm to be used
- The hash algorithm to be used

During the key exchange, the server identifies itself to the client with a *host key*. If the client has never communicated with this particular server before, the server's key will be unknown to the client and it will not connect. OpenSSH gets around this problem by accepting the server's host key after the user is notified and verifies that he will accept the new host key. In subsequent connections, the server's host key is checked against the saved version on the client, providing confidence that the client is indeed communicating with the intended server. If, in the future, the host key no longer matches, the user must remove the client's saved version before a connection can occur.

Caution

It is possible for an attacker to masquerade as the SSH server during the initial contact since the local system does not know the difference between the intended server and a false one set up by an attacker. To help prevent this you should verify the integrity of a new SSH server by contacting the server administrator before connecting for the first time or after a host key has changed.

SSH is designed to work with almost any kind of public key algorithm or encoding format. After an initial key exchange creates a hash value used for exchanges and a shared secret value, the two systems immediately begin calculating new keys and algorithms to protect authentication and future data sent over the connection.

After a certain amount of data has been transmitted using a given key and algorithm (the exact amount depends on the SSH implementation), another key exchange occurs, which generates another set of hash values and a new shared secret value. Even if an attack is able to determine the hash and shared secret value, he would have to determine this information each time a new key exchange is made in order to monitor the communication.

9.3.2. Authentication

Once the transport layer has constructed a secure tunnel to pass information between the two systems, the server tells the client the different authentication methods supported, such as using a private key-encoded signature or typing a password. The client will then try to authenticate itself to the server using any of the supported methods.

Servers can be configured to allow different types of authentication, which gives each side the optimal amount of control. The server can decide which encryption methods it will support based on its security model, and the client can choose the order of authentication methods to attempt from among the available options. Thanks to the secure nature of the SSH transport layer, even seemingly insecure authentication methods, such as a host-based authentication, are safe to use.

Most users requiring a secure shell will authenticate using a password. Since the password is encrypted when moving over the the transport layer, it can be safely sent across any network.

9.3.3. Connection

After a successful authentication over the SSH transport layer, multiple *channels* are opened by multiplexing⁴ the single connection between the two systems. Each of these channels handles communication for different terminal sessions, forwarded X11 sessions, or other services seeking to use the SSH connection.

Both clients and servers can create a new channel. Each channel is then assigned a different number for each end of the connection. When the client attempts to open a new channel, the clients sends the channel number along with the request. This information is stored by the server and is used to direct communication to that channel. This is done so that different types of sessions will not affect one another and so that when a given session ends, its channel can be closed without disrupting the primary SSH connection.

Channels also support *flow-control*, which allows them to send and receive data in an orderly fashion. In this way, data is not sent over the channel until the client receives a message that the channel is open.

The client and server negotiate the characteristics of each channel automatically, depending on the type of service the client requests and the way the user is connected to the network. This allows great flexibility in handling different types of remote connections without having to change the basic infrastructure of the protocol.

9.4. OpenSSH Configuration Files

OpenSSH has two different sets of configuration files: one for client programs (`ssh`, `scp`, and `sftp`) and one for the server daemon (`sshd`).

System-wide SSH configuration information is stored in the `/etc/ssh/` directory:

- `moduli` — Contains Diffie-Hellman groups used for the Diffie-Hellman key exchange which is critical for constructing a secure transport layer. When keys are exchanged at the beginning of an SSH session, a shared, secret value is created which cannot be determined by either party alone. This value is then used to provide host authentication.
- `ssh_config` — The system-wide default SSH client configuration file. It is overridden if one is also present in the user's home directory (`~/.ssh/config`).
- `sshd_config` — The configuration file for the `sshd` daemon.
- `ssh_host_dsa_key` — The DSA private key used by the `sshd` daemon.
- `ssh_host_dsa_key.pub` — The DSA public key used by the `sshd` daemon.
- `ssh_host_key` — The RSA private key used by the `sshd` daemon for version 1 of the SSH protocol.

4. A multiplexed connection consists of several signals being sent over a shared, common medium. With SSH, different channels are sent over a common secure connection.

- `ssh_host_key.pub` — The RSA public key used by the `sshd` daemon for version 1 of the SSH protocol.
- `ssh_host_rsa_key` — The RSA private key used by the `sshd` daemon for version 2 of the SSH protocol.
- `ssh_host_rsa_key.pub` — The RSA public key used by the `sshd` for version 2 of the SSH protocol.

User-specific SSH configuration information is stored in the user's home directory within the `~/.ssh/` directory:

- `authorized_keys` — This file holds a list of "authorized" public keys for servers. When the client connects to a server, the server authenticates the client by checking its signed public key stored within this file. This is an optional authentication method.
- `id_dsa` — Contains the DSA authentication identity of the user.
- `id_dsa.pub` — The DSA public key of the user.
- `id_rsa` — The RSA public key used by `sshd` for version 2 of the SSH protocol.
- `identity` — The RSA private key used by `sshd` for version 1 of the SSH protocol.
- `known_hosts` — This file contains DSA host keys of SSH servers accessed by the user. This file is very important for ensuring that the SSH client is connecting the correct SSH server. If a host's key has changed, and you are not absolutely certain why, you should contact the system administrator of the SSH server to make sure that the server has not been compromised. If a server's host keys are legitimately altered by a re-installation of Red Hat Linux the next time you log into that server you will be notified that the host key stored in the `known_hosts` file does not match. To connect to the server, the user must open the `known_hosts` file in a text editor and delete the key for that host. This allows the SSH client to create a new host key.

See the man pages for `ssh` and `sshd` for information concerning the various directives available in the SSH configuration files.

9.5. More Than a Secure Shell

A secure command line interface is just the beginning of the many ways SSH can be used. Given the proper amount of bandwidth, X11 sessions can be directed over an SSH channel. Or, by using TCP/IP forwarding, previously insecure port connections between systems can be mapped to specific SSH channels.

9.5.1. X11 Forwarding

Opening an X11 session over an established SSH connection is as easy as running an X program on the local machine. When an X program is run from the secure shell prompt, the SSH client and server create a new secure channel, and the X program data is sent over that channel to your client machine transparently.

X11 forwarding can be very useful. For example, you can use X11 forwarding to create a secure, interactive session with `up2date` on the server to update packages. To do this, connect to the server using `ssh` and type:

```
up2date &
```

You will be asked to supply the root password for the server. Then, **Red Hat Update Agent** will appear and you can update your packages on the server as though you were sitting in front of the machine.

9.5.2. Port Forwarding

With SSH you can secure otherwise insecure TCP/IP protocols via port forwarding. When using this technique, the SSH server becomes an encrypted conduit to the SSH client.

Port forwarding works by mapping a local port on the client to a remote port on the server. SSH allows you to map any port from the server to any port on the client; the port numbers do not need to match for it to work.

To create a TCP/IP port forwarding channel which listens for connections on the localhost, use the following command:

```
ssh -L local-port:remote-hostname:remote-port username@hostname
```

Note

Setting up port forwarding to listen on ports below 1024 requires root access.

So if you want to check your email on a server called `mail.domain.com` using POP through an encrypted connection, you can use the following command:

```
ssh -L 1100:mail.domain.com:110 mail.domain.com
```

Once the port forwarding channel is in place between your machine and the mail server, you can direct a POP mail client to use port 1100 on localhost to check for new mail. Any requests sent to port 1100 on your system will be directed securely to the `mail.domain.com` server.

If `mail.domain.com` is not running an SSH server daemon, but you can log in via SSH to a machine on the same network, you can still use SSH to secure the part of the POP connection. However, a slightly different command is necessary:

```
ssh -L 1100:mail.domain.com:110 other.domain.com
```

In this example, POP requests from port 1100 on your machine are forwarded through the SSH connection on port 22 to the ssh server, `other.domain.com`. Then, `other.domain.com` connects to port 110 on `mail.domain.com` to allow you to check for new mail. Note that by using this technique, only the connection between your system and `other.domain.com` is secure.

Port forwarding can also be used to get information securely through network firewalls. If the firewall is configured to allow SSH traffic via its standard port (22) but block access to other ports, a connection between two hosts using the blocked ports is still possible by redirecting their communication over an established SSH connection.

Note

Using port forwarding to forward connections in this manner allows any user on the client system to connect to the service to which you are forwarding connections. If the client system becomes compromised, the attacker will also have access to forwarded services.

System administrators concerned about port forwarding can disable this functionality on the server by specifying a `No` parameter for the `AllowTcpForwarding` line in `/etc/ssh/sshd_config` and restarting the `sshd` service.

9.6. Require SSH for Remote Connections

For SSH to be truly effective in protecting your network connections, you must stop using all insecure connection protocols, such as `telnet` and `rsh`. Otherwise, a user's password may be protected using `ssh` for one log in only to be captured when he logs in again using `telnet`.

To disable insecure connection methods to your system, use the command line program `chkconfig`, the ncurses-based program `ntsysv`, or the graphical application **Services Configuration Tool** (`redhat-config-services`). All of these tools require root access.

Some services to disable include:

- `telnet`
- `rsh`
- `ftp`
- `rlogin`
- `wu-ftp`
- `vsftpd`

For more information on runlevels and configuring services with `chkconfig`, `ntsysv`, and **Services Configuration Tool**, refer to the chapter titled *Controlling Access to Services* in the *Official Red Hat Linux Customization Guide*.

Kerberos

Kerberos is a network authentication protocol created by MIT which uses secret-key cryptography — obviating the need to send passwords over the network. By authenticating using Kerberos, unauthorized users trying to intercept passwords on the network are effectively thwarted.

10.1. Advantages of Kerberos

Most conventional network systems use password-based authentication schemes. When a user authenticates to a network server, he must supply a user name and password for each service requiring authentication. This information is sent over the network, and the server verifies their identity using this information.

However, the transmission of authentication information for many services is in plain text. An attacker with access to the network and a packet analyzer, also known as a packet sniffer, can intercept any passwords sent in this manner.

The primary design goal of Kerberos is to eliminate the transmission across the network of authentication information. The proper use of Kerberos effectively eliminates the threat packet sniffers would otherwise pose on a network.

10.2. Kerberos Disadvantages

Although Kerberos removes a common and severe security threat, it may be difficult to implement for various reasons:

- Migrating user passwords from a standard UNIX password database, such as `/etc/passwd` or `/etc/shadow`, to a Kerberos password database can be tedious as there is no automated mechanism to perform this task. For more information, refer to question number 2.23 in the Kerberos FAQ at the following URL: <http://www.nrl.navy.mil/CCS/people/kenh/kerberos-faq.html>.
- Kerberos has only partial compatibility with the Pluggable Authentication Modules (PAM) system used by most servers running Red Hat Linux. For more information on this issue, see Section 10.5.
- For an application to use Kerberos, its source must be modified to make the appropriate calls into the Kerberos libraries. For some applications, this can be quite problematic due to size or frequency that krb libraries must be called. For other applications, changes must be made to the way in which the server and client side communicate. Again, this may require extensive programming. Closed-source applications that do not have Kerberos support by default are often the most problematic.
- Kerberos assumes that you are using trusted hosts on an untrusted network. Its primary goal is to prevent plain text passwords from being sent across that network. However, if anyone other than the proper user has physical access to any of the hosts, especially the one that issues tickets used for authentication, the entire Kerberos authentication system is at risk of being compromised.
- Kerberos is an all or nothing solution. If you decide to use Kerberos on your network, you must remember any passwords transferred to a service which does not use Kerberos for authentication run the risk of being captured by packet sniffers. Thus, your network gains no benefit from the use of Kerberos. To secure your network with Kerberos, you must either *kerberize all* applications which send plain text passwords or do not use those applications on your network at all.

10.3. Kerberos Terminology

Like any other system, Kerberos has its own terminology to define various aspects of the service. Before learning how the service works, it is important to learn the following terms.

ciphertext

Encrypted data.

plain text

Unencrypted, human-readable data.

client

An entity on the network (a user, a host, or an application) that can get a ticket from Kerberos.

credential cache or ticket file

A file which contains the keys for encrypting communications between a user and various network services. Kerberos 5 supports a framework for using other cache types, such as shared memory, but files are more thoroughly supported.

crypt hash

A one way hash used to authenticate users. While more secure than plain text, it is fairly easy to decrypt for an experienced cracker.

key

Data used when encrypting or decrypting other data. Encrypted data cannot be decrypted without the proper key or extremely good guessing.

Key Distribution Center (KDC)

A service that issues Kerberos tickets, usually run on the same host as the Ticket Granting Server

key table or keytab

A file that includes an unencrypted list of principals and their keys. Servers retrieve the keys they need from keytab files instead of using `kinit`. The default keytab file is `/etc/krb5.keytab`. The `/usr/kerberos/sbin/kadmind` command is the only service that uses any other file (it uses `/var/kerberos/krb5kdc/kadm5.keytab`).

principal

A user or service that can authenticate using Kerberos. A principal's name is in the form `root[/instance]@REALM`. For a typical user, the `root` is the same as their login ID. The `instance` is optional. If the principal has an instance, it is separated from the `root` with a forward slash (`/`). An empty string (`""`) is considered a valid instance (which differs from the default `NULL` instance), but using it can be confusing. All principals in a realm have their own key, which is derived from their password or randomly set for services.

realm

A network that uses Kerberos, composed of one or more servers called KDCs and a potentially large number of clients.

service

A program accessed over the network.

ticket

A temporary set of electronic credentials that verify the identity of a client for a particular service.

Ticket Granting Service (TGS)

A server that issues tickets for a desired service which are in turn given to users for access to the service. The TGS usually runs on the same host as the KDC

Ticket Granting Ticket (TGT)

A special ticket that allows the client to obtain additional tickets without applying for them from the KDC.

10.4. How Kerberos Works

Now that the Kerberos terminology has been defined, the following is an overview of how the Kerberos authentication system works.

Rather than authentication occurring between each client machine and each server, Kerberos uses symmetric encryption and a trusted third party — known as the Key Distribution Center or KDC — to authenticate users on a network to a suite of services on a network. Once authenticated, Kerberos stores a ticket specific to that session on the user's machine and any kerberized service will look for this ticket rather than asking the user to authenticate using a password.

When a user on a kerberized network logs in to their workstation, their principal is sent to the Key Distribution Center as a request for a Ticket Granting Ticket (TGT). This request can be sent by the login program so that it is transparent to the user or can be sent by the `kinit` program after the user logs in.

The KDC checks for the principal in its database. If the principal is found, the KDC creates a TGT, encrypts it using the user's key and sends it back to the user.

The login program on the client machine or `kinit` decrypts the TGT using the user's key (which it computes from the user's password). The TGT is set to expire after a certain period of time and stored in the client machine's credentials cache. The expiration time is set so a compromised TGT can only be used for a certain period of time (usually eight hours). This is safer than tradition password model because the password is never passed over the network. Once the TGT is issued, the user will not have to re-enter their password to the KDC until the TGT expires or they logout and login again.

When the user needs access to a network service, the client uses the TGT to request a ticket for the service from the Ticket Granting Service (TGS), which runs on the KDC. The TGS issues a ticket for the desired service, which is then used to authenticate the user.

Warning

The Kerberos system can be compromised anytime any user on the network authenticates against a non-kerberized service by sending a password in plain text. Therefore use of non-kerberized services should be discouraged. Such services include **telnet** and **ftp**. Use of other secure protocols, such as SSH or SSL secured services, however, is acceptable.

This, of course, is a broad overview of how Kerberos authentication on a network would typically work. For a more in-depth look at Kerberos authentication, refer to Section 10.8.

**Note**

Kerberos depends on certain network services to work correctly. First, Kerberos requires approximate clock synchronization between the machines on the network. Therefore, a clock synchronization program should be set up for the network, such as `ntpd`.

Also, since certain aspects of Kerberos rely on the Domain Name Service (DNS), be sure that the DNS entries and hosts on the network are all properly configured. See the Kerberos V5 System Administrator's Guide, provided in PostScript and HTML formats in `/usr/share/doc/krb5-server-version-number`, (where `version-number` is the version installed on the system) for more information.

10.5. Kerberos and PAM

Currently, kerberized services do not make use of Pluggable Authentication Modules (PAM) — kerberized servers bypass PAM completely. However, applications that use PAM can make use of Kerberos for authentication if the `pam_krb5` module (provided in the `pam_krb5` package) is installed. The `pam_krb5` package contains sample configuration files that allow services like `login` and `gdm` to authenticate users and obtain initial credentials using their passwords. If access to network servers is always done using kerberized services or services that use GSS-API, like IMAP, the network can be considered reasonably safe.

Careful administrators will not add Kerberos password checking to all network services because most of the protocols used by these services do not encrypt the password before sending it over the network.

The next section will describe how to set up a basic Kerberos server.

10.6. Configuring a Kerberos 5 Server

When you are setting up Kerberos, install the server first. If you need to set up slave servers, the details of setting up relationships between master and slave servers are covered in the *Kerberos 5 Installation Guide* located in the `/usr/share/doc/krb5-server-<version-number>` directory.

To configure a basic Kerberos server, follow these steps:

1. Be sure that you have clock synchronization and DNS working on your server before configuring Kerberos 5. Pay particular attention to time synchronization between the Kerberos server and its various clients. If the server and client clocks are different by more than five minutes (this default amount is configurable in Kerberos 5), Kerberos clients will not be able to authenticate to the server. This clock synchronization is necessary to prevent an attacker from using an old Kerberos ticket to masquerade as a valid user.

You should set up a Network Time Protocol (NTP) compatible client/server network under, even if you are not using Kerberos. Red Hat Linux 8.0 includes the `ntp` package for easy installation. See <http://www.eccis.udel.edu/~ntp> for additional information on NTP.

2. Install the `krb5-libs`, `krb5-server`, and `krb5-workstation` packages on the dedicated machine which will run your KDC. This machine needs to be very secure — if possible, it should not run any services other than the KDC.

If you would like to use a Graphical User Interface utility to administrate Kerberos, you should also install the `gnome-kerberos` package. It contains `krb5`, a GUI tool for managing tickets.

3. Edit the `/etc/krb5.conf` and `/var/kerberos/krb5kdc/kdc.conf` configuration files to reflect your realm name and domain-to-realm mappings. A simple realm can be constructed by replacing instances of `EXAMPLE.COM` and `example.com` with your domain name — being certain to keep uppercase and lowercase names in the correct format — and by changing the

KDC from *kerberos.example.com* to the name of your Kerberos server. By convention, all realm names are uppercase and all DNS hostnames and domain names are lowercase. For full details on the formats of these files, see their respective man pages.

4. Create the database using the `kdb5_util` utility from a shell prompt:

```
/usr/kerberos/sbin/kdb5_util create -s
```

The `create` command creates the database that will be used to store keys for your Kerberos realm. The `-s` switch forces creation of a *stash* file in which the master server key is stored. If no stash file is present from which to read the key, the Kerberos server (`krb5kdc`) will prompt the user for the master server password (which can be used to regenerate the key) every time it starts.

5. Edit the `/var/kerberos/krb5kdc/kadm5.acl` file. This file is used by `kadmind` to determine which principals have access to the Kerberos database and their level of access. Most organizations will be able to get by with a single line:

```
*/admin@EXAMPLE.COM *
```

Most users will be represented in the database by a single principal (with a *NULL*, or empty, instance, such as *joe@EXAMPLE.COM*). With this configuration, users with a second principal with an instance of *admin* (for example, *joeladmin@EXAMPLE.COM*) will be able to wield full power over the realm's Kerberos database.

Once `kadmind` is started on the server, any user will be able to access its services by running `kadmin` on any of the clients or servers in the realm. However, only users listed in the `kadm5.acl` file will be able to modify the database in any way, except for changing their own passwords.

Note

The `kadmin` utility communicates with the `kadmind` server over the network, and they use Kerberos to handle authentication. Of course, you need to create the first principal before you can connect to the server over the network to administer it. Create the first principal with the `kadmin.local` command, which is specifically designed to be used on the same host as the KDC and does not use Kerberos for authentication.

Type the following `kadmin.local` command at the KDC terminal to create the first principal:

```
/usr/kerberos/sbin/kadmin.local -q "addprinc username/admin"
```

6. Start Kerberos using the following commands:

```
/sbin/service krb5kdc start
/sbin/service kadmind start
/sbin/service krb524 start
```

7. Add principals for your users using the `addprinc` command with `kadmin.kadmin` and `kadmin.local` on the master KDC are a command line interfaces to the Kerberos administration system. As such, many commands are available after launching the `kadmin` program. Please see the `kadmin` man page for more information.

8. Verify that your server will issue tickets. First, run `kinit` to obtain a ticket and store it in a credential cache file. Then use `klist` to view the list of credentials in your cache and use `kdestroy` to destroy the cache and the credentials it contains.

Note

By default, `kinit` attempts to authenticate using the login user name of the account you used when you first logged into your system (not the Kerberos server). If that system user name does not correspond to a principal in the Kerberos database, you will receive an error message. If that happens, supply `kinit` with the name of your principal as an argument on the command line (`kinit principal`).

Once you have completed the steps listed above, the Kerberos server should be up and running. Next, we will set up a Kerberos client.

10.7. Configuring a Kerberos 5 Client

Setting up a Kerberos 5 client is less involved than setting up a server. At minimum, install the client packages and provide each client with a valid `krb5.conf` configuration file. Kerberized versions of `rsh` and `rlogin` will also require some configuration changes.

1. Be sure that you have time synchronization in place between the Kerberos client and KDC. See Section 10.6 for more information. In addition, verify that DNS is working properly on the Kerberos client before configuring the Kerberos client programs.
2. Install the `krb5-libs` and `krb5-workstation` packages on all of the client machines. You must supply a version of `/etc/krb5.conf` for each client; usually this can be the same `krb5.conf` used by the KDC.
3. Before a workstation in the realm can allow users to connect using kerberized `rsh` and `rlogin`, that workstation will need to have the `xinetd` package installed and have its own host principal in the Kerberos database. The `kshd` and `klogind` server programs will also need access to the keys for their service's principal.

Using `kadmin`, add a host principal for the workstation on the KDC. The instance in this case will be the hostname of the workstation. You can use the `-randkey` option to `kadmin`'s `addprinc` command *on the KDC* to create the principal and assign it a random key:

```
addprinc -randkey host/blah.example.com
```

Now that you have created the principal, you can extract the keys for the workstation by running `kadmin` *on the workstation itself*, and using the `ktadd` command within `kadmin`:

```
ktadd -k /etc/krb5.keytab host/blah.example.com
```

In order to use the kerberized versions of `rsh` and `rlogin`, you must enable `klogin`, `eklogin`, and `kshell`.¹

4. Other kerberized network services will need to be started. To use kerberized `telnet`, you must enable `krb5-telnet`.

To provide FTP access, create and extract a key for a principal with a root of `ftp`, with the instance set to the hostname of the FTP server. Then enable `gssftp`.

The IMAP server included in the `imap` package will use GSS-API authentication using Kerberos 5 if it finds the proper key in `/etc/krb5.keytab`. The root for the principal should be `imap`. The CVS `gserver` uses a principal with a root of `cv`s and is otherwise identical to a `pserver`.

10.8. Additional Resources

For more information on Kerberos, refer to the following resources.

1. Refer to the chapter titled *Controlling Access to Services* in the *Official Red Hat Linux Customization Guide* for details on enabling services.

10.8.1. Installed Documentation

- `/usr/share/doc/krb5-server-<version-number>` — The *Kerberos V5 Installation Guide* and the *Kerberos V5 System Administrator's Guide* in PostScript and HTML formats. You must have the `krb5-server` RPM package installed.
- `/usr/share/doc/krb5-workstation-<version-number>` — The *Kerberos V5 UNIX User's Guide* in PostScript and HTML formats. You must have the `krb5-workstation` RPM package installed.

10.8.2. Useful Websites

- <http://web.mit.edu/kerberos/www> — *Kerberos: The Network Authentication Protocol* webpage from MIT.
- <http://www.nrl.navy.mil/CCS/people/kenh/kerberos-faq.html> — The Kerberos Frequently Asked Questions (FAQ).
- <ftp://athena-dist.mit.edu/pub/kerberos/doc/usenix.PS> — The PostScript version of *Kerberos: An Authentication Service for Open Network Systems* by Jennifer G. Steiner, Clifford Neuman, and Jeffrey I. Schiller. This document is the original paper describing Kerberos.
- <http://web.mit.edu/kerberos/www/dialogue.html> — *Designing an Authentication System: a Dialogue in Four Scenes* originally by Bill Bryant in 1988, modified by Theodore Ts'o in 1997. This document is a conversation between two developers who are thinking through the creation of a Kerberos-style authentication system. The conversational style of the discussion make this a good starting place for people who are completely unfamiliar with Kerberos.
- <http://www.ornl.gov/~jar/HowToKerb.html> — *How to Kerberize your Site*.
- <http://www.networkcomputing.com/netdesign/kerb1.html> — *Kerberos Network Design Manual* is a thorough overview of the Kerberos system.

Tripwire data integrity assurance software monitors the reliability of critical system files and directories by identifying changes made to them. Tripwire configuration options include the ability to receive alerts via email if particular files are altered and automated integrity checking via a `cron` job. Using Tripwire for intrusion detection and damage assessment helps you keep track of system changes. Because Tripwire can positively identify files that have been added, modified, or deleted, it can speed recovery from a break-in by keeping the number of files which must be restored to a minimum.

Tripwire compares files and directories against a database of file locations, dates modified, and other data. The database contains *baselines*, which are snapshots of specified files and directories at a specific point in time. The contents of the baseline database should be generated before the system is at risk of intrusion. After creating the baseline database, Tripwire then compares the current system to the baseline and reports any modifications, additions, or deletions.

While Tripwire is a valuable tool for auditing the security state of Red Hat Linux systems, Tripwire is not supported by Red Hat, Inc. Refer to the Tripwire project's website (<http://www.tripwire.org>) for more information about Tripwire.

11.1. How to Use Tripwire

The following flowchart illustrates how Tripwire works:

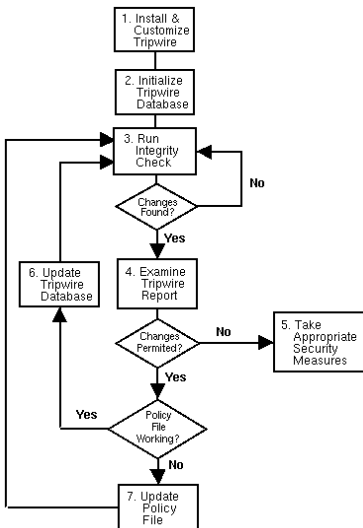

Figure 11-1. Using Tripwire

The following describes in more detail the numbered blocks shown in Figure 11-1

1. Install Tripwire and customize the policy file.

Install the `tripwire` RPM (Section 11.2). Then, customize the sample configuration and policy files (`/etc/tripwire/twcfg.txt` and `/etc/tripwire/twpol.txt` respectively) and run the configuration script, `/etc/tripwire/twinstall.sh`. For more information, see Section 11.3.

2. Initialize the Tripwire database.

Build a database of critical system files to monitor based on the contents of the new, signed Tripwire policy file, `/etc/tripwire/tw.pol`. For more information, see Section 11.4.

3. Run a Tripwire integrity check.

Compare the newly-created Tripwire database with the actual system files, looking for missing or altered files. For more information, see Section 11.5.

4. Examine the Tripwire report file.

View the Tripwire report file using `/usr/sbin/twprint` to note integrity violations. For more information, see Section 11.6.1.

5. If unauthorized integrity violations occur, take appropriate security measures.

If monitored files have been altered inappropriately, you can either replace the original files from backup copies reinstall the program, or completely reinstall the operating system.

6. If the file alterations were valid, verify and update the Tripwire database file.

If the changes made to monitored files are intentional, edit Tripwire's database file to ignore those changes in subsequent reports. For more information, see Section 11.7.

7. If the policy file fails verification, update the Tripwire policy file.

To change the list of files Tripwire monitors or how it treats integrity violations, update the supplied policy file (`/etc/tripwire/twpol.txt`), regenerate a signed copy (`/etc/tripwire/tw.pol`), and update the Tripwire database. For more information, see Section 11.8.

Refer to the appropriate sections within this chapter for detailed instructions on each step.

11.2. Installing the Tripwire RPM

The easiest way to install Tripwire is to select the `tripwire` RPM during the Red Hat Linux 8.0 installation process. However, if you have already installed Red Hat Linux 8.0, you can use `rpm` or **Package Management Tool** (`redhat-config-packages`) to install the Tripwire RPM from the Red Hat Linux 8.0 CD-ROMs.

If you are not sure whether or not Tripwire is installed, type the following command at a shell prompt:

```
rpm -q tripwire
```

If Tripwire is installed, this command will return the following:

```
tripwire-<version-number>
```

The following steps outline how to find and install Tripwire from CD-ROM using the RPM command line application:

1. Insert *CD 2* of the Red Hat Linux 8.0 installation CD-ROMs.

- If the CD-ROM does not automatically mount, type the following command:

```
mount /mnt/cdrom
```

- Verify that the `tripwire` RPM is on the CD-ROM by typing:

```
ls /mnt/cdrom/RedHat/RPMS/ | grep tripwire
```

If the RPM is on the CD-ROM, this command will display the package name.

If the RPM is *not* on the CD-ROM, the shell prompt will return. In this case, you will need to check *CD 3* and, possibly, *CD 1* of the Red Hat Linux 8.0 installation CD-ROMs by first unmounting the CD-ROM then repeating steps one through three.

Unmount the CD-ROM by right-clicking on the CD-ROM icon and selecting **Eject** or by typing the following command at the shell prompt:

```
umount /mnt/cdrom
```

- Once you have located the `tripwire` RPM, install it by typing the following command as the root user:

```
rpm -Uvh /mnt/cdrom/RedHat/RPMS/tripwire*.rpm
```

In the `/usr/share/doc/tripwire-<version-number>/` directory, you will find release notes and README files for Tripwire. These documents contain important information about the default policy file and other topics.

11.3. Customizing Tripwire

After you have installed the Tripwire RPM, you need to complete the following steps to initialize the software:

11.3.1. Edit `/etc/tripwire/twcfg.txt`

Although you are not required to edit this sample Tripwire configuration file, you may find it necessary for your situation. For instance you may want to alter the location of Tripwire files, customize email settings, or customize the level of detail for reports.

Below is a list of *required* user configurable variables in the `/etc/tripwire/twcfg.txt` file:

- POLFILE** — Specifies the location of the policy file; `/etc/tripwire/tw.pol` is the default value.
- DBFILE** — Specifies the location of the database file; `/var/lib/tripwire/$(HOSTNAME).twd` is the default value.
- REPORTFILE** — Specifies the location of the report files. By default this value is set to `/var/lib/tripwire/report/$(HOSTNAME)-$(DATE).twr`.
- SITEKEYFILE** — Specifies the location of the site key file; `/etc/tripwire/site.key` is the default value.
- LOCALKEYFILE** — Specifies the location of the local key file; `/etc/tripwire/$(HOSTNAME)-local.key` is the default value.

Important

If you edit the configuration file and leave any of the above variables undefined, the configuration file will be invalid. If this occurs, when you execute the `tripwire` command it will report an error and exit.

The rest of the configurable variables in the sample `/etc/tripwire/twcfg.txt` file are optional. These include the following:

- **EDITOR** — Specifies the text editor called by Tripwire. The default value is `/bin/vi`.
- **LATEPROMPTING** — If set to `true` this variable configures Tripwire to wait as long as possible before prompting the user for a password, thereby minimizing the amount of time the password is in memory. The default value is `false`.
- **LOOSEDIRECTORYCHECKING** — If set to `true` this variable configures Tripwire to report if a file within a watched directory changes and not to report the change for the directory itself. This limits redundancy in Tripwire reports. The default value is `false`.
- **SYSLOGREPORTING** — If set to `true`, this variable configures Tripwire to report information to the syslog daemon via the "user" facility. The log level is set to `notice`. See the `syslogd` man page for more information. The default value is `false`.
- **MAILNOVIOLATIONS** — If set to `true` this variable configures Tripwire to email a report at a regular interval regardless of whether or not any violations have occurred. The default value is `true`.
- **EMAILREPORTLEVEL** — Specifies the level detail for emailed reports. Valid values for this variable are 0 through 4. The default value is 3.
- **REPORTLEVEL** — Specifies the level detail for reports generated by the `twprint` command. This value can be overridden on the command line, but is set to 3 by default.
- **MAILMETHOD** — Specifies which mail protocol Tripwire should use. Valid values are `SMTP` and `SENDMAIL`. The default value is `SENDMAIL`.
- **MAILPROGRAM** — Specifies which mail program Tripwire should use. The default value is `/usr/sbin/sendmail -oi -t`.

After editing the sample configuration file, you will need to configure the sample policy file.

Warning

For security purposes, you should either delete or store in a secure location any copies of the plain text `/etc/tripwire/twcfg.txt` file after running the installation script or regenerating a signed configuration file. Alternatively, you can change the permissions so that it is not world readable.

11.3.2. Edit `/etc/tripwire/twpol.txt`

Although it is not required, you should edit this heavily commented sample Tripwire policy file to take into account the specific applications, files, and directories on your system. Relying on the unaltered sample configuration from the RPM may not adequately protect your system.

Modifying the policy file also increases the usefulness of Tripwire reports by minimizing false alerts for files and programs you are not using and by adding functionality, such as email notification.

Note

Notification via email is not configured by default. See Section 11.8.1 for more on configuring this feature.

If you modify the sample policy file after running the configuration script, see Section 11.8 for instructions on regenerating a signed policy file.

 **Warning**

For security purposes, you should either delete or store in a secure location any copies of the plain text `/etc/tripwire/twpol.txt` file after running the installation script or regenerating a signed configuration file. Alternatively, you can change the permissions so that it is not world readable.

11.3.3. Run the `twinstall.sh` Script

As the root user, type `/etc/tripwire/twinstall.sh` at the shell prompt to run the configuration script. The `twinstall.sh` script will ask you for site and local passwords. These passwords are used to generate cryptographic keys for protecting Tripwire files. The script then creates and signs these files.

When selecting the site and local passwords, you should consider the following guidelines:

- Use at least eight alphanumeric and symbolic characters, but for each password do not exceed 1023.
- Do not use quotes in a password.
- Make the Tripwire passwords completely different from the root or any other password for the system.
- Use unique passwords for both the site key and the local key.

The site key password protects the Tripwire configuration and policy files. The local key password protects the Tripwire database and report files.

 **Warning**

There is no way to decrypt a signed file if you forget your password. If you forget the passwords, the files are unusable and you will have to run the configuration script again.

By encrypting its configuration, policy, database, and report files, Tripwire protects them from being viewed by anyone who does not know the site and local passwords. This means that, even if an intruder obtains root access to your system, they will not be able to alter the Tripwire files to hide their tracks.

Once encrypted and signed, the configuration and policy files generated by running the `twinstall.sh` script should not be renamed or moved.

11.4. Initialize the Tripwire Database

Initialize the Tripwire database file by issuing the `/usr/sbin/tripwire --init` command at the command line.

When initializing its database, Tripwire builds a collection of file system objects based on the rules in the policy file. This database serves as the baseline for integrity checks.

To initialize the Tripwire database, use the following command:

```
/usr/sbin/tripwire --init
```

This command can take several minutes to run.

Once you finish these steps successfully, Tripwire has the baseline snapshot of your file system necessary to check for changes in critical files. After initializing the Tripwire database, you should run

an initial integrity check. This check should be done prior to connecting the computer to the network, and putting it into production. For instructions on doing this see Section 11.5.

Once Tripwire is configured to your satisfaction, you are free to place the system into production.

11.5. Running an Integrity Check

By default the Tripwire RPM adds a shell script called `tripwire-check` to the `/etc/cron.daily/` directory. This will automatically run an integrity check once per day.

You can, however, run a Tripwire integrity check at any time by typing the following command:

```
/usr/sbin/tripwire --check
```

During an integrity check, Tripwire compares the current state of file system objects with the properties recorded in its database. Violations are printed to the screen and an encrypted copy of the report is created in `/var/lib/tripwire/report/`. You can view the report using the `twprint` command as outlined in Section 11.6.1.

If you would like to receive an email when certain types of integrity violations occur, you can configure this in the policy file. See Section 11.8.1 for instructions on how to set up and test this feature.

11.6. Examining Tripwire Reports

The `/usr/sbin/twprint` command is used to view encrypted Tripwire reports and databases.

11.6.1. Viewing Tripwire Reports

The `twprint -m r` command will display the contents of a Tripwire report in clear text. You must, however, tell `twprint` which report file to display.

A `twprint` command for printing Tripwire reports looks similar to the following:

```
/usr/sbin/twprint -m r --twrfile /var/lib/tripwire/report/<name>.twr
```

The `-m r` option in the command directs `twprint` to decode a Tripwire report. The `--twrfile` option directs `twprint` to use a specific Tripwire report file.

The name of the Tripwire report that you want to see includes the name of the host that Tripwire checked to generate the report, plus the creation date and time. You can review previously saved reports at any time. Simply type `ls /var/lib/tripwire/report` to see a list of Tripwire reports.

Tripwire reports can be rather lengthy, depending upon the number of violations found or errors generated. A sample report starts off like this:

```
Tripwire(R) 2.3.0 Integrity Check Report
```

```
Report generated by:      root
Report created on:       Fri Jan 12 04:04:42 2001
Database last updated on: Tue Jan  9 16:19:34 2001
```

```
=====
Report Summary:
=====
```

```
Host name:                some.host.com
Host IP address:          10.0.0.1
Host ID:                  None
Policy file used:         /etc/tripwire/tw.pol
Configuration file used:  /etc/tripwire/tw.cfg
```

```
Database file used:      /var/lib/tripwire/some.host.com.twd
Command line used:     /usr/sbin/tripwire --check
```

```
=====
Rule Summary:
=====
```

```
-----
Section: Unix File System
-----
```

Rule Name	Severity Level	Added	Removed	Modified
Invariant Directories	69	0	0	0
Temporary directories	33	0	0	0
* Tripwire Data Files	100	1	0	0
Critical devices	100	0	0	0
User binaries	69	0	0	0
Tripwire Binaries	100	0	0	0

11.6.2. View Tripwire Databases

You can also use `twprint` to view the entire database or information about selected files in the Tripwire database. This is useful for seeing just how much information Tripwire is tracking on your system.

To view the entire Tripwire database, type this command:

```
/usr/sbin/twprint -m d --print-dbfile | less
```

This command will generate a large amount of output, with the first few lines appearing similar to this:

```
Tripwire(R) 2.3.0 Database
```

```
Database generated by:    root
Database generated on:   Tue Jan  9 13:56:42 2001
Database last updated on: Tue Jan  9 16:19:34 2001
```

```
=====
Database Summary:
=====
```

```
Host name:                some.host.com
Host IP address:          10.0.0.1
Host ID:                  None
Policy file used:         /etc/tripwire/tw.pol
Configuration file used:  /etc/tripwire/tw.cfg
Database file used:       /var/lib/tripwire/some.host.com.twd
Command line used:       /usr/sbin/tripwire --init
```

```
=====
Object Summary:
=====
```

```
-----
# Section: Unix File System
-----
```

Mode	UID	Size	Modify Time
/			
drwxr-xr-x	root (0)	XXX	XXXXXXXXXXXXXXXXXXXX
/bin			
drwxr-xr-x	root (0)	4096	Mon Jan 8 08:20:45 2001

```

/bin/arch
-rwxr-xr-x root (0) 2844 Tue Dec 12 05:51:35 2000
/bin/ash
-rwxr-xr-x root (0) 64860 Thu Dec 7 22:35:05 2000
/bin/ash.static
-rwxr-xr-x root (0) 405576 Thu Dec 7 22:35:05 2000

```

To see information about a particular file that Tripwire is tracking, such as `/etc/hosts`, use the following command:

```
/usr/sbin/twprint -m d --print-dbfile /etc/hosts
```

The result will look similar to this:

```

Object name: /etc/hosts

Property:          Value:
-----
Object Type       Regular File
Device Number     773
Inode Number      216991
Mode              -rw-r--r--
Num Links         1
UID               root (0)
GID               root (0)

```

See man page for `twprint` for more options.

11.7. Updating the Tripwire Database

If you run an integrity check and Tripwire finds violations, you will first need to determine whether the violations discovered are actual security breaches or the product of authorized modifications. If you recently installed an application or edited critical system files, Tripwire will correctly report integrity check violations. In this case, you should update your Tripwire database so those changes are no longer reported as violations. However, if unauthorized changes are made to system files that generate integrity check violations, then you should restore the original file from a backup, reinstall the program, or, if the breach is severe enough, completely reinstall the operating system.

To update the Tripwire database so it accepts valid policy violations, Tripwire first cross-references a report file against the database, then integrates into it valid violations from the report file. When updating the database, be sure to use the most recent report.

Use the following command to update the Tripwire database, where *name* is the name of the most recent report file:

```
/usr/sbin/tripwire --update --twrfile /var/lib/tripwire/report/<name>.twr
```

Tripwire will display the report file using the default text editor specified on the `EDITOR` line of the Tripwire configuration file. This gives you an opportunity to deselect files you do not wish to update in the Tripwire database.

**Important**

It is important that you change only *authorized* integrity violations in the database.

All proposed updates to the Tripwire database start with an [x] before the file name, similar to the following example:

```
Added:
[x] "/usr/sbin/longrun"

Modified:
[x] "/usr/sbin"
[x] "/usr/sbin/cpqarrayd"
```

If you want to specifically exclude a valid violation from being added to the Tripwire database, remove the x. To accept any files with an x beside them as changes.

To edit files in the default text editor, vi, type i and press [Enter] to enter insert mode and make any necessary changes. When finished press the [Esc] key, type :wq, and press [Enter].

After the editor closes, enter your local password and the database will be rebuilt and signed.

After a new Tripwire database is written, the newly authorized integrity violations will no longer show up as warnings.

11.8. Updating the Tripwire Policy File

If you want to change the files Tripwire records in its database, change email configuration, or modify the severity at which certain violations are reported, you need to edit your Tripwire policy file.

First, make whatever changes are necessary to the sample policy file `/etc/tripwire/twpol.txt`. If you deleted this file (as you should whenever you are finished configuring Tripwire), you can regenerate it by issuing the following command:

```
twadmin --print-polfile > /etc/tripwire/twpol.txt
```

A common change to this policy file is to comment out any files that do not exist on your system so that they will not generate a file not found error in your Tripwire reports. For example, if your system does not have a `/etc/smb.conf` file, you can tell Tripwire not to try to look for it by commenting out its line in `twpol.txt` with the # character as in the following example:

```
# /etc/smb.conf -> $(SEC_CONFIG) ;
```

Next, you must generate a new, signed `/etc/tripwire/tw.pol` file and generate an updated database file based on this policy information. Assuming `/etc/tripwire/twpol.txt` is the edited policy file, use this command:

```
/usr/sbin/twadmin --create-polfile -S site.key /etc/tripwire/twpol.txt
```

You will be asked for the site password. Then, the `twpol.txt` file will be encrypted and signed.

It is important that you update the Tripwire database after creating a new `/etc/tripwire/tw.pol` file. The most reliable way to accomplish this is to delete your current Tripwire database and create a new database using the new policy file.

If your Tripwire database file is named `bob.domain.com.twd`, type this command:

```
rm /var/lib/tripwire/bob.domain.com.twd
```

Then type the following command to create a new database using the updated policy file:

```
/usr/sbin/tripwire --init
```

To make sure the database was correctly changed, run the first integrity check manually and view the contents of the resulting report. See Section 11.5 and Section 11.6.1 for more on doing these tasks.

11.8.1. Tripwire and Email

You can configure Tripwire to send an email to one or more accounts if a specific type of policy is violated. In order to do this, you need to figure out what policy rules should be monitored and who should get the email when those rules are broken. Note that on large systems with multiple administrators, you can have different sets of people notified depending on the types of violations.

Once you have determined who to notify and what rule violations to report to them, edit the `/etc/tripwire/twpol.txt` file, adding an `emailto=` line to the rule directive section for each appropriate rule. Do this by adding a comma after the `severity=` line and putting `emailto=` on the next line, followed by one or more email addresses. More than one email address can be specified if the addresses are separated by a semi-colon.

For example, if two administrators, Johnray and Bob, need to be notified if a networking program is modified, change the Networking Programs rule directive in the policy file to look like this:

```
(
  rulename = "Networking Programs",
  severity = $(SIG_HI),
  emailto = johnray@domain.com;bob@domain.com
)
```

After changing the policy file, follow the instructions in Section 11.8 to generate an updated, encrypted and signed copy of the Tripwire policy file.

11.8.1.1. Sending Test Email Messages

To test Tripwire's email notification configuration, use the following command:

```
/usr/sbin/tripwire --test --email your@email.address
```

A test email will immediately be sent to the email address by the `tripwire` program.

11.9. Updating the Tripwire Configuration File

If you want to change Tripwire's configuration file, you should first edit the sample configuration file `/etc/tripwire/twcfg.txt`. If you deleted this file (as you should whenever you are finished configuring Tripwire), you can regenerate it by issuing the following command:

```
twadmin --print-cfgfile > /etc/tripwire/twcfg.txt
```

Tripwire will not recognize any configuration changes until the configuration text file is correctly signed and converted to `/etc/tripwire/tw.pol` with the `twadmin` command.

Use the following command to regenerate a configuration file from the `/etc/tripwire/twcfg.txt` text file:

```
/usr/sbin/twadmin --create-cfgfile -S site.key /etc/tripwire/twcfg.txt
```

Since the configuration file does not alter any Tripwire policies or files tracked by the application, it is not necessary to regenerate the Tripwire database.

11.10. Tripwire File Location Reference

Before working with Tripwire, you should know where important files for the application are located. Tripwire stores its files in a variety of places depending on their role.

- Within the `/usr/sbin/` directory you will find the following programs:
 - `tripwire`
 - `twadmin`
 - `twprint`
- Within the `/etc/tripwire/` directory you will find the following files:
 - `twinstall.sh` — The initialization script for Tripwire.
 - `twcfg.txt` — The sample configuration file supplied by the Tripwire RPM.
 - `tw.cfg` — The signed configuration file created by the `twinstall.sh` script.
 - `twpol.txt` — The sample policy file supplied by the Tripwire RPM.
 - `tw.pol` — The signed policy file created by the `twinstall.sh` script.
 - Key Files — The local and site keys created by the `twinstall.sh` script which end with a `.key` file extension.
- After running the `twinstall.sh` installation script you will find the following files in the `/var/lib/tripwire/` directory:
 - The Tripwire Database — The database of your system's files which has a `.twd` file extension.
 - Tripwire Reports — The `report/` directory is where Tripwire reports are stored.

The next section explains more about the roles these files play in the Tripwire system.

11.10.1. Tripwire Components

The following describes in more detail the roles the listed in the previous section play in the Tripwire system.

/etc/tripwire/tw.cfg

This is the encrypted Tripwire configuration file which stores system-specific information, such as the location of Tripwire data files. The `twinstall.sh` installer script and `twadmin` command generates this file using the information in the text version of the configuration file, `/etc/tripwire/twcfg.txt`.

After running the the installation script, the system administrator can change parameters by editing `/etc/tripwire/twcfg.txt` and regenerating a signed copy of the `tw.cfg` file using the `twadmin` command. See Section 11.9 for more information on how to do this.

```
/etc/tripwire/tw.pol
```

The active Tripwire policy file is an encrypted file containing comments, rules, directives, and variables. This file dictates the way Tripwire checks your system. Each rule in the policy file specifies a system object to be monitored. Rules also describe which changes to the object to report and which to ignore.

System objects are the files and directories you wish to monitor. Each object is identified by an object name. A property refers to a single characteristic of an object that Tripwire software can monitor. Directives control conditional processing of sets of rules in a policy file. During installation, the sample text policy file, `/etc/tripwire/twpol.txt`, is used to generate the active Tripwire policy file.

After running the the installation script, the system administrator can update the Tripwire policy file by editing `/etc/tripwire/twpol.txt` and regenerating a signed copy of the `tw.pol` file using the `twadmin` command. See Section 11.8 for more information on how to do this.

```
/var/lib/tripwire/host_name.twd
```

When first initialized, Tripwire uses the signed policy file rules to create this database file. The Tripwire database is a baseline snapshot of the system in a known secure state. Tripwire compares this baseline against the current system to determine what changes have occurred. This comparison is called an *integrity check*.

```
/var/lib/tripwire/report/host_name-date_of_report-time_of_report.twr
```

When you perform an integrity check, Tripwire produces report files in the `/var/lib/tripwire/report/` directory. The report files summarize any file changes that violated the policy file rules during the integrity check. Tripwire reports are named using the following convention: `host_name-date_of_report-time_of_report.twr`. These reports detail the differences between the Tripwire database and your actual system files.

11.11. Additional Resources

Tripwire can do more than what is covered in this chapter. Refer to these additional sources for more information about Tripwire.

11.11.1. Installed Documentation

- `/usr/share/doc/tripwire-<version-number>` — An excellent starting point for learning about how to customize the configuration and policy files in the `/etc/tripwire/` directory.
- Also, refer to the man pages for `tripwire`, `twadmin` and `twprint` for help using those utilities.

11.11.2. Useful Websites

- <http://www.tripwire.org> — The home of the Tripwire Open Source Project, where you can find the latest news on the application, including a helpful FAQ.
- http://sourceforge.net/project/showfiles.php?group_id=3130 — This links to the latest official documentation from the Tripwire project.

Network Services Reference

Network Scripts

Using Red Hat Linux, all network communications occur between configured *interfaces* and physical networking devices connected to the system. The different types of interfaces that exist are as varied as the physical devices they support.

The configuration files for network interfaces and the scripts to activate and deactivate them are located in the `/etc/sysconfig/network-scripts/` directory. While the existence of interface files can differ from system to system, the three different types of files that exist in this directory, *interface configuration files*, *interface control scripts*, and *network function files*, work together to enable Red Hat Linux to use various network devices.

This chapter will explore the relationship between these files and how they are used.

12.1. Network Configuration Files

Before we review the interface configuration files themselves, let us itemize the primary configuration files used by Red Hat Linux to configure networking. Understanding the role these files play in setting up the network stack can be helpful when customizing your system.

The primary network configuration files are as follows:

- `/etc/hosts` — The main purpose of this file is to resolve hostnames that cannot be resolved any other way. It can also be used on resolve hostnames on small networks with no DNS server. Regardless of the type of network the computer is on, this file should contain a line specifying the IP address of the loopback device (127.0.0.1) as `localhost.localdomain`. For more information see the `hosts` man page.
- `/etc/resolv.conf` — This file specifies the IP addresses of DNS servers and the search domain. Unless configured to do otherwise, the network initialization scripts populate this file. For more information on this file see the `resolv.conf` man page.
- `/etc/sysconfig/network` — Specifies routing and host information for all network interfaces. For more information on this file and what directives it accepts, see Section 3.7.1.23.
- `/etc/sysconfig/network-scripts/ifcfg-<interface-name>` — For each network interface on a Red Hat Linux system, there is a corresponding interface configuration script. Each of these files provide information specific to a particular network interface. See Section 12.2 for more information on this type of file and what directives it accepts.

Caution

The `/etc/sysconfig/networking/` directory is used by the **Network Administration Tool** (`redhat-config-network`) and its contents should not be edited manually. For more information about configuring network interfaces using the **Network Administration Tool**, see the chapter called *Network Configuration* in the *Official Red Hat Linux Customization Guide*.

12.2. Interface Configuration Files

Interface configuration files control the operation of individual network interface device. As your Red Hat Linux system boots, it uses these files to determine what interfaces to bring up and how to

configure them. These files are usually named `ifcfg-<name>`, where *<name>* refers to the name of the device that the configuration file controls.

12.2.1. Ethernet Interfaces

One of the most common interface files is `ifcfg-eth0`, which controls the first *network interface card* or *NIC* in the system. In a system with multiple NICs, you will also have multiple `ifcfg-eth` files, each one with a unique number at the end of the file name. Because each device has its own configuration file, you can control how each interface functions individually.

Below is a sample `ifcfg-eth0` file for a system using a fixed IP address:

```
DEVICE=eth0
BOOTPROTO=none
ONBOOT=yes
NETWORK=10.0.1.0
NETMASK=255.255.255.0
IPADDR=10.0.1.27
USERCTL=no
```

The values required in an interface configuration file can change based on other values. For example, the `ifcfg-eth0` file for an interface using DHCP looks quite a bit different, because IP information is provided by the DHCP server:

```
DEVICE=eth0
BOOTPROTO=dhcp
ONBOOT=yes
```

Most of the time you will probably want to use a GUI utility, such as **Network Administration Tool** (`redhat-config-network`) to make changes to the various interface configuration files. See the *Official Red Hat Linux Customization Guide* for instructions on using this tool.

You can also edit the configuration file for a given network interface by hand. Below is a listing of the parameters one can expect to configure in an interface configuration file.

Within each of the interface configuration files, the following values are common:

- `BOOTPROTO=<protocol>`, where *<protocol>* is one of the following:
 - `none` — No boot-time protocol should be used.
 - `bootp` — The BOOTP protocol should be used.
 - `dhcp` — The DHCP protocol should be used.
- `BROADCAST=<address>`, where *<address>* is the broadcast address. This directive is deprecated.
- `DEVICE=<name>`, where *<name>* is the name of the physical device (except dynamically-allocated PPP devices where it is the *logical name*).
- `DNS{1,2}=<address>`, where *<address>* is a name server address to be placed in `/etc/resolv.conf` if the `PEERDNS` directive is set to `yes`.
- `IPADDR=<address>`, where *<address>* is the IP address.
- `NETMASK=<mask>`, where *<mask>* is the netmask value.
- `NETWORK=<address>`, where *<address>* is the network address. This directive is deprecated.
- `ONBOOT=<answer>`, where *<answer>* is one of the following:

- `yes` — This device should be activated at boot-time.
 - `no` — This device should not be activated at boot-time.
- `PEERDNS=<answer>`, where `<answer>` is one of the following:
 - `yes` — Modify `/etc/resolv.conf` if the DNS directive is set. If you are using DHCP, then `yes` is the default.
 - `no` — Do not modify `/etc/resolv.conf`.
 - `SRCADDR=<address>`, where `<address>` is the specified source IP address for outgoing packets.
 - `USERCTL=<answer>`, where `<answer>` is one of the following:
 - `yes` — Non-root users are allowed to control this device.
 - `no` — Non-root users are not allowed to control this device.

12.2.2. Dialup Interfaces

If you connect to the Internet via PPP dialup connection, you need a configuration file for that interface as well.

This file is created automatically for you when you use `wvdial`, **Network Administration Tool** or **Kppp** to create a dialup account. In addition, any changes to dialup account settings are reflected in these interface configuration files. The *Official Red Hat Linux Getting Started Guide* contains instructions for using these GUI-based dialup connection tools. You can also create and edit this file manually. A typical `ifcfg-ppp0` files looks like this:

```
DEVICE=ppp0
NAME=test
WVDIALSECT=test
MODEMPORT=/dev/modem
LINESPEED=115200
PAPNAME=test
USERCTL=true
ONBOOT=no
PERSIST=no
DEFROUTE=yes
PEERDNS=yes
DEMAND=no
IDLETIMEOUT=600
```

Serial Line Internet Protocol (SLIP) is another dialup interface, although it is less commonly used. SLIP files have interface configuration file names such as `ifcfg-sl0`.

Among the options not already discussed that may be used in these files:

- `DEFROUTE=<answer>`, where `<answer>` is one of the following:
 - `yes` — Set this interface as the default route.
 - `no` — Do not set this interface as the default route.
- `DEMAND=<answer>`, where `<answer>` is one of the following:

- `yes` — This interface will allow `pppd` to initiate a connection when someone attempts to use it.
 - `no` — A connection must be manually established for this interface.
- `IDLETIMEOUT=<value>`, where `<value>` is the number of seconds of idle activity before the interface will disconnect itself.
 - `INITSTRING=<string>`, where `<string>` is the initialization string passed to the modem device. This option is primarily used with SLIP interfaces.
 - `LINESPEED=<value>`, where `<value>` is the baud rate of the device. Possible standard values here include 57600, 38400, 19200, and 9600.
 - `MODEMPORT=<device>`, where `<device>` is the name of the serial device that is used to establish the connection for the interface.
 - `MTU=<value>`, where `<value>` is the *Maximum Transfer Unit (MTU)* setting for the interface. The MTU refers to the largest number of bytes of data a frame can carry, not counting its header information. In some dialup situations, setting this to a value of 576 will result in fewer dropped packets and slightly improve the throughput for a connection.
 - `NAME=<name>`, where `<name>` is the reference to the title given to a collection of dialup connection configurations.
 - `PAPNAME=<name>`, where `<name>` is the username given during the *Password Authentication Protocol (PAP)* exchange that occurs to allow you to connect to a remote system.
 - `PEERDNS=<answer>`, where `<answer>` is one of the following:
 - `yes` — Modify the system's `/etc/resolv.conf` file entries to use the DNS servers provided by the remote system when a connection is established.
 - `no` — The `/etc/resolv.conf` file will not be modified.
 - `PERSIST=<answer>`, where `<answer>` is one of the following:
 - `yes` — This interface should be kept active at all times, even if deactivated after a modem hang up.
 - `no` — This interface should not be kept active at all times.
 - `REMIP=<address>`, where `<address>` is the remote system's IP address. This is usually left unspecified.
 - `WVDIALSECT=<name>`, where `<name>` associates this interface with a dialer configuration in `/etc/wvdial.conf`, which contains the phone number to be dialed and other important information for the interface.

12.2.3. Other Interfaces

Other common interface configuration files that use these options include `ifcfg-lo`, which controls the IP protocol's local loopback device, `ifcfg-irlan0`, which arranges settings for the first infrared device, `ifcfg-plip0`, which controls the first PLIP device, and `ifcfg-tr0`, used with the first Token Ring device.

A local *loopback interface* is often used in testing, as well as a variety of applications that require an IP address pointing back to the same system. Any data sent to the loopback device is immediately returned to the host's network layer.

**Warning**

Never edit the loopback interface script, `/etc/sysconfig/network-scripts/ifcfg-lo`, by hand. Doing so can prevent the system from operating correctly.

An *infrared interface* allows information between devices, such as a laptop and a printer, to flow over an infrared link which works in a similar way to an Ethernet device except that it commonly occurs over a peer-to-peer connection.

A *Parallel Line Interface Protocol (PLIP)* connection works much the same way, except that it utilizes a parallel port.

Token Ring topologies are not as common on Local Area Networks as they once were, having been eclipsed by Ethernet.

12.2.4. Alias and Clone Files

Two lesser-used types of interface configuration files found in the `/etc/sysconfig/network-scripts/` directory are *alias* and *clone* files.

Alias interface configuration files take names in the format of `ifcfg-<if-name>:<alias-value>`, and they allow an alias to point to an interface. For example, a `ifcfg-eth0:0` file could be configured to specify `DEVICE=eth0:0` and a static IP address of `10.0.0.2`, serving as an alias of an Ethernet interface already configured to receive its IP information via DHCP in `ifcfg-eth0`. At that point, the `eth0` device is bound to a dynamic IP address, but it can always be referred to on that system via the fixed `10.0.0.2` IP address.

A clone interface configuration file should follow this naming convention, `ifcfg-<if-name>-<clone-name>`. While an alias file is another way to refer to an existing interface configuration file, a clone file is used to specify additional options when specifying an interface. For example, if you have a standard DHCP Ethernet interface called `eth0`, it may look similar to this:

```
DEVICE=eth0
ONBOOT=yes
BOOTPROTO=dhcp
```

Since `USERCTL` is set to `no` if it is not specified, users cannot bring this interface up and down. To give users this ability, create a clone by copying `ifcfg-eth0` to `ifcfg-eth0-user` and add the following line:

```
USERCTL=yes
```

When a user brings up the `eth0` interface with the `ifup eth0-user` command, the configuration options from `ifcfg-eth0` and `ifcfg-eth0-user` are combined. While this is a very basic example, this method can be used with a variety of options and interfaces.

The easiest way to create alias and clone interface configuration files is to use the graphical network configuration tool, **Network Administration Tool**. For more on using this tool, see the chapter called *Network Configuration* in the *Official Red Hat Linux Customization Guide*.

12.3. Interface Control Scripts

The interface control scripts activate and deactivate system interfaces. There are two primary interface control scripts, `/sbin/ifdown` and `/sbin/ifup`, that call on control scripts located in the `/etc/sysconfig/network-scripts/` directory.

The two interface control scripts are `ifdown` and `ifup` and are symbolic links to scripts in the `/sbin/` directory. When either of these scripts are called, they require a value of the interface to be specified, such as:

```
ifup eth0
Determining IP information for eth0... done.
```

At that point, the `/etc/rc.d/init.d/functions` and `/etc/sysconfig/network-scripts/network-functions` files are used to perform a variety of tasks. See Section 12.4 for more information.

After verifying that an interface has been specified and that the user executing the request is allowed to control the interface, the correct script for the type of interface device brings the interface up or down. The following interface control scripts are the most common:

- `ifup-aliases` — Configures IP aliases from interface configuration files when more than one IP address is associated with an interface.
- `ifdown-cipcb` and `ifup-cipcb` — Used to bring *Crypto IP Encapsulation (CIPE)* connections up and down.
- `ifdown-ipv6` and `ifup-ipv6` — Contains IPv6-related function calls using environment variables in various interface configuration files and `/etc/sysconfig/network`.
- `ifup-ixp` — Used to bring up an IPX interface.
- `ifup-plib` — Used to bring up a PLIP interface.
- `ifup-plusb` — Used to bring up a USB interface for network connections.
- `ifdown-post` and `ifup-post` — Contains commands to be executed after an interface is brought up or down.
- `ifdown-ppp` and `ifup-ppp` — Used to bring a PPP interface up or down.
- `ifup-routes` — Adds static routes for a device as its interface is brought up.
- `ifdown-sit` and `ifup-sit` — Contains function calls related to bringing up and down an IPv6 tunnel within an IPv4 connection.
- `ifdown-sl` and `ifup-sl` — Used to bring an SLIP interface up or down.

Be aware that removing or modifying any scripts in the `/etc/sysconfig/network-scripts/` directory can cause interface connections to act strangely or fail, as these scripts. Only advanced users should modify scripts related to a network interface.

You can also use the `init` script `/etc/rc.d/init.d/network` to activate and deactivate all network interfaces configured to start at boot time with the command:

```
/sbin/service network action
```

Where `action` is either `start`, `stop`, or `restart`. You can also use the command `/sbin/service/network status` to view a list of configured devices and currently active devices.

12.4. Network Functions

Red Hat Linux makes use of several files that contain important functions that are used in various ways to bring interfaces up and down. Rather than forcing each interface control file to contain the same functions as another, these functions are grouped together in a few files that can be sourced when needed.

The most common network functions file is `network-functions`, located in the `/etc/sysconfig/network-scripts/` directory. This file contains a variety of common IPv4 functions useful to many interface control scripts, such as contacting running programs that have requested information about changes in an interface's status, setting host names, finding a gateway device, seeing if a particular device is down or not, and adding a default route.

As the functions required for IPv6 interfaces are different than IPv4 interfaces, a `network-functions-ipv6` file exists specifically to hold this information. IPv6 support must be enabled in the kernel in order to communicate via that protocol. A function is present in this file that checks for the presence of IPv6 support. Additionally, functions that configure and delete static IPv6 routes, create and remove tunnels, add and remove IPv6 addresses to an interface, and test for the existence of an IPv6 address on an interface can also be found in this file.

12.5. Additional Resources

More information concerning network scripts can be found in the following places.

- `/usr/share/doc/initscripts-<version>/sysconfig.txt` — A comprehensive guide to available options for network configuration files, including IPv6 options not covered in this chapter.
- `/usr/share/doc/iproute-<version>/ip-cref.ps` — This Postscript™ file contains a wealth of information about the `ip` command, which can be used to manipulate routing tables, among other things. Use `ghostview` or `kghostview` to look at this file.

Firewalls and `iptables`

Linux comes with advanced tools for *packet filtering* — the process of controlling network packets as they enter, move through, and exit the network stack within the kernel. Pre-2.4 kernels relied on `ipchains` for packet filtering and used lists of rules applied to packets at each step of the filtering process. The introduction of the 2.4 kernel brought with it `iptables` (also called *netfilter*), which is similar to `ipchains` but greatly expands on the scope and control available for filtering network packets.

This chapter focuses on packet filtering basics, defines the differences between `ipchains` and `iptables`, explains various options available with `iptables` commands, and shows how filtering rules can be preserved between system reboots.

If you require instructions for constructing `iptables` rules or setting up a firewall based on these rules, please see Section 13.5 for more information.

Warning

The default firewall mechanism under the 2.4 kernel is `iptables`, but `iptables` cannot be used if `ipchains` are already running. If `ipchains` are present at boot time, the kernel will issue an error and fail to start `iptables`.

The functionality of `ipchains` is not affected by these errors.

13.1. Packet Filtering

Traffic moves through a network in *packets*. A network packet is collection of data in a specific size and format. In order to transmit a file over a network, the sending computer must first break the file into packets using the rules of the network protocol. Each of these packets holds a small part of the file data. Upon receiving the transmission, the target computer reassembles the packets into the file.

Every packet contains information which helps it navigate the network and move toward its destination. The packet can tell computers along the way, as well as the destination machine, where it came from, where it is going, and what type of packet it is, among other things. Most packets are designed to carry data, although some protocols use packets in special ways. For example, the *Transmission Control Protocol (TCP)* uses a SYN packet, which contains no data, to initiate communication between two systems.

The Linux kernel contains the built-in ability to filter packets, allowing some of them into the system while stopping others. The 2.4 kernel's netfilter has three built-in *tables* or *rules lists*. They are as follows:

- `filter` — This is the default table for handling network packets.
- `nat` — This table used to alter packets that create a new connection.
- `mangle` — This table is used for specific types of packet alteration.

Each of these tables in turn have a group of built-in *chains* which correspond to the actions performed on the packet by the netfilter.

The built-in chains for the `filter` table are as follows:

- `INPUT` — This chain applies to packets received via a network interface.

- *OUTPUT* — This chain applies to packets sent out via the same network interface which received the packets.
- *FORWARD* — This chain applies to packets received on one network interface and sent out on another.

The built-in chains for the `nat` table are as follows:

- *PREROUTING* — This chain alters packets received via a network interface when they arrive.
- *OUTPUT* — This chain alters locally-generated packets before they are routed via a network interface.
- *POSTROUTING* — This chain alters packets before they are sent out via a network interface.

The built-in chains for the `mangle` table are as follows:

- *PREROUTING* — This chain alters packets received via a network interface before they are routed.
- *OUTPUT* — This chain alters locally-generated packets before they are routed via a network interface.

Every network packet received by or sent out of a Linux system is subject to at least one table.

A packet may be checked against multiple rules within each rules list before emerging at the end of the chain. The structure and purpose of these rules may vary, but they usually seek to identify a packet coming from or going to a particular IP address or set of addresses when using a particular protocol and network service.

Regardless of their destination, when packets match a particular rule on one of the tables, they are designated for a particular *target* or action to be applied to them. If the rule specifies an `ACCEPT` target for a matching packet, the packet skips the rest of the rule checks and is allowed to continue to its destination. If a rule specifies a `DROP` target, that packet is refused access to the system and nothing is sent back to the host that sent the packet. If a rule specifies a `REJECT` target, the packet is dropped, but an error packet is sent to the packet's originator.

Every chain has a default policy to `ACCEPT`, `DROP`, `REJECT`, or `QUEUE` the packet to be passed to user-space. If none of the rules in the chain apply to the packet, then the packet is dealt with in accordance with the default policy.

The `iptables` command allows you to configure these rule lists, as well as set up new tables to be used for your particular situation.

13.2. Differences between `iptables` and `ipchains`

At first glance, `ipchains` and `iptables` appear to be quite similar. Both methods of packet filtering use chains of rules operating within the Linux kernel to decide not only which packets to let in or out, but also what to do with packets that match certain rules. However, `iptables` offers a much more extensible way of filtering packets, giving the administrator a greater amount of control without building too much complexity into the entire system.

Specifically, users comfortable with `ipchains` should be aware of the following significant differences between `ipchains` and `iptables` before attempting to use `iptables`:

- *Under `iptables`, each filtered packet is processed using rules from only one chain rather than multiple chains.* For instance, a `FORWARD` packet coming into a system using `ipchains` would have to go through the `INPUT`, `FORWARD`, and `OUTPUT` chains in order to move along to its destination. However, `iptables` only sends packets to the `INPUT` chain if they are destined for the local system and only sends them to the `OUTPUT` chain if the local system generated the

packets. For this reason, you must be sure to place the rule designed to catch a particular packet in the rule that will actually see the packet.

The advantage is that you now have more control over the disposition of each packet. If you are attempting to block access to a particular website, it is now possible to block access attempts from clients running on hosts which use your host as a gateway. An OUTPUT rule which denies access will no longer prevent access for hosts which use your host as a gateway.

- *The DENY target has been changed to DROP.* In `ipchains`, packets that matched a rule in a chain could be directed to the DENY target, which silently dropped the packet. This target must be changed to DROP in `iptables` to have the same effect.
- *Order matters when placing options in a rule.* Previously, with `ipchains`, it did not matter very much how you ordered the rule options. The `iptables` command is a bit pickier about where some options may go. For example, you must now specify the source or destination port after the protocol (ICMP, TCP, or UDP) to be used in a rule.
- *When specifying network interfaces to be used with a rule, you must only use incoming interfaces (-i option) with INPUT or FORWARD chains and outgoing interfaces (-o option) with FORWARD or OUTPUT chains.* This is necessary because OUTPUT chains are no longer used by incoming interfaces, and INPUT chains are not seen by packets moving through outgoing interfaces.

This is by no means a comprehensive list of the changes, given that `iptables` represents a fundamentally rewritten network filter. For more specific information, consult the *Linux 2.4 Packet Filtering HOWTO* and the sources found in Section 13.5.

13.3. Options Used in iptables Commands

Rules that allow packets to be filtered by the kernel are put in place by running the `iptables` command. When using the `iptables` command, you must specify the following options:

- *Packet Type* — This dictates what type of packets the command filters.
- *Packet Source or Destination* — This dictates what packets the command filters based on the source or destination of the packet.
- *Target* — This dictates what action is taken on packets matching the above criteria.

The options used with given `iptables` rule must be grouped logically, based on the purpose and conditions of the overall rule, in order for the rule to be valid.

13.3.1. Tables

A powerful aspect of `iptables` is that multiple tables can be used to decide the fate of a particular packet, depending upon the type of packet being monitored and what is to be done with the packet. Thanks to the extensible nature of `iptables`, specialized tables can be created and stored in the `/etc/modules/<kernel-version>/kernel/net/ipv4/netfilter/` directory to meet specific goals. Think of `iptables` as being able to run multiple sets of `ipchains` rules in defined chains, with each set fulfilling a particular role.

The default table, named `filter`, contains the standard built-in INPUT, OUTPUT, and FORWARD chains. This is somewhat similar to the standard chains in use with `ipchains`. However, by default, `iptables` also includes two additional tables that perform specific packet filtering jobs. The `nat` table can be used to modify the source and destination addresses recorded in packets, and the `mangle` table allows you to alter packets in specialized ways.

Each table contains default chains that perform necessary tasks based on the purpose of the table, but you can easily set up new chains in each of the tables.

13.3.2. Structure

Many iptables commands have the following structure:

```
iptables [-t <table-name>] <command> <chain-name> <parameter-1> \
  <option-1> <parameter-n> <option-n>
```

In this example, the `<table-name>` option allows the user to select a table other than the default `filter` table to use with the command. The `<command>` option is the center of the command, dictating a specific action to perform, such as appending or deleting a rule from a particular chain, which is specified by the `<chain-name>` option. Following the `<chain-name>` are pairs of parameters and options that actually define the way the rule will work and what will happen when a packet matches the rule.

When looking at the structure of an iptables command, it is important to remember that, unlike most other commands, the length and complexity of an iptables command can change based on its purpose. A simple command to remove a rule from a chain can be very short, while a command designed to filter packets from a particular subnet using a variety of specific parameters and options can be rather lengthy. When creating iptables commands it is helpful to recognize that some parameters and options may create the need for other parameters and options to further specify the previous option's request. In order to construct a valid rule, this must continue until every parameter and option that requires another set of options is satisfied.

Type `iptables -h` to see a comprehensive list of iptables command structures.

13.3.3. Commands

Commands tell iptables to perform a specific action. Only one command is allowed per iptables command string. With the exception of the help command, all commands are written in upper-case characters.

The iptables commands are as follows:

- `-A` — Appends the iptables rule to the end of the specified chain. This is the command used to simply add a rule when rule order in the chain does not matter.
- `-C` — Checks a particular rule before adding it to the user-specified chain. This command can help you construct complicated iptables rules by prompting you for additional parameters and options.
- `-D` — Deletes a rule in a particular chain by number (such as 5 for the fifth rule in a chain). You can also type the entire rule, and iptables will delete the rule in the chain that matches it.
- `-E` — Renames a user-defined chain. This does not affect the structure of the table. Rather, it just saves you the trouble of deleting the chain, creating it under the new name, and reconfiguring all of your rules for that chain.
- `-F` — Flushes the selected chain, which effectively deletes every rule in the the chain. If no chain is specified, this command flushes every rule from every chain.
- `-h` — Provides a list of helpful command structures, as well as a quick summary of command parameters and options.
- `-I` — Inserts a rule in a chain at a particular point. Assign a number to the rule to be inserted and iptables will put it there. If no number is specified, iptables will place your command at the top of the rule list.

**Caution**

Be aware of which option (`-A` or `-I`) you are using when adding a rule. The order of the rules can be very important when determining if a particular packet applies to one rule or another. Make sure when adding a rule to the beginning or end of the chain that it does not affect other rules in that chain.

- `-L` — Lists all of the rules in the chain specified after the command. To list all rules in all chains in the default `filter` table, do not specify a chain or table. Otherwise, the following syntax should be used to list the rules in a specific chain in a particular table:

```
iptables -L <chain-name> -t <table-name>
```

Powerful options for the `-L` command that provide rule numbers and allow more verbose rule descriptions, among others, are described in Section 13.3.7.

- `-N` — Creates a new chain with a user-specified name.
- `-P` — Sets the default policy for a particular chain, so that when packets traverse an entire chain without matching a rule, they will be sent on to a particular target, such as `ACCEPT` or `DROP`.
- `-R` — Replaces a rule in a particular chain. You must use a rule's number after the chain's name to replace that rule. The first rule in a chain relates to rule number 1.
- `-X` — Deletes a user-specified chain. Deleting a built-in chain for any table is not allowed.
- `-Z` — Zeros the byte and packet counters in all chains for a particular table.

13.3.4. Parameters

Once certain `iptables` commands are specified, including those used to add, append, delete, insert, or replace rules within a particular chain, parameters are required to begin the construction of the packet filtering rule.

- `-c` — Resets the counters for a particular rule. This parameter accepts the `PKTS` and `BYTES` options to specify what counter to reset.
- `-d` — Sets the destination hostname, IP address, or network of a packet that will match the rule. When matching a network, you can use two different methods for signifying the netmask, such as `192.168.0.0/255.255.255.0` or `192.168.0.0/24`.

- `-f` — Applies this rule only to fragmented packets.

By using the `!` option after this parameter, only unfragmented packets will be matched.

- `-i` — Sets the incoming network interface, such as `eth0` or `ppp0`, to use with a particular rule. With `iptables`, this optional parameter may only be used with the `INPUT` and `FORWARD` chains when used with the `filter` table and the `PREROUTING` chain with the `nat` and `mangle` tables.

This parameter features several useful options that may be used before specifying the name of an interface:

- `!` — Tells this parameter not to match, meaning that any specified interfaces are specifically excluded from this rule.
- `+` — A wildcard character used to match all interfaces which match a particular string. For example, the parameter `-i eth+` would apply this rule to any Ethernet interfaces on your system but exclude any other interfaces, such as `ppp0`.

If the `-i` parameter is used but no interface is specified, then every interface is affected by the rule.

- `-j` — Tells `iptables` to jump to a particular target when a packet matches a particular rule. Valid targets to be used after the `-j` option include the standard options, `ACCEPT`, `DROP`, `QUEUE`, and `RETURN`, as well as extended options that are available through modules loaded by default with the Red Hat Linux `iptables` RPM package, such as `LOG`, `MARK`, and `REJECT`, among others. See the

iptables man page for more information on these and other targets, including rules regarding their use.

You may also direct a packet matching this rule to a user-defined chain outside of the current chain. This allows you to apply other rules against this packet, further filtering it with more specific criteria.

If no target is specified, the packet moves past the rule with no action taken. However, the counter for this rule is still increased by one, as the packet matched the specified rule.

- `-o` — Sets the outgoing network interface for a particular rule, and may only be used with OUTPUT and FORWARD chains in the `filter` table and the POSTROUTING chain in the `nat` and `mangle` tables. This parameter's options are the same as those of the incoming network interface parameter (`-i`).
- `-p` — Sets the IP protocol for the rule, which can be either `icmp`, `tcp`, `udp`, or `all`, to match every supported protocol. In addition, lesser used protocols listed in `/etc/protocols` may also be used. If this option is omitted when creating a rule, the `all` option is the default.
- `-s` — Sets the source for a particular packet, using the same syntax as the destination (`-d`) parameter.

13.3.5. Match Options

Different network protocols provide specialized matching options which may be set in specific ways to match a particular packet using that protocol. Of course, the protocol must first be specified in the `iptables` command, such as using `-p tcp <protocol-name>`, to make the options for that protocol available.

13.3.5.1. TCP Protocol

These match options are available for the TCP protocol (`-p tcp`):

- `--dport` — Sets the destination port for the packet. You can use either a network service name (such as `www` or `smtp`), port number, or range of port numbers to configure this option. To browse the names and aliases of network services and the port numbers they use, view the `/etc/services` file. You can also use `--destination-port` to specify this match option.

To specify a specific range of port numbers, separate the two numbers with a colon (:), such as `-p tcp --dport 3000:3200`. The largest valid range is `0:65535`.

You may also use an exclamation point character (!) as a flag after the `--dport` option to tell `iptables` to match all packets which *do not* use that network service or port.

- `--sport` — Sets the source port of the packet, using the same options as `--dport`. You can also use `--source-port` to specify this match option.
- `--syn` — Applies to all TCP packets designed to initiate communication, commonly called *SYN packets*. Any packets that carry a data payload are not touched. Placing an exclamation point character (!) as a flag after the `--syn` option causes all non-SYN packets to be matched.
- `--tcp-flags` — Allows TCP packets with specific bits, or flags, set to be matched with a rule. The `--tcp-flags` match option accepts two parameters after it, which are flags for the various bits arranged in a comma-separated list. The first parameter is the mask, which sets the flags to be examined on the packet. The second parameter refers to the flags that must be set in the packet to make a match. The possible flags are `ACK`, `FIN`, `PSH`, `RST`, `SYN`, and `URG`. In addition, `ALL` and `NONE` can also be used to match every flag or none of them.

For example, an `iptables` rule which contains `-p tcp --tcp-flags ACK,FIN,SYN SYN` will only match TCP packets that have the SYN flag set and the ACK and FIN flags unset.

Like many other options, using the exclamation point character (!) after `--tcp-flags` reverses the effect of the match option, so that the second parameter's flags must not be set in order to match.

- `--tcp-option` — Attempts to match with TCP-specific options that can be set within a particular packet. This match option can also be reversed with the exclamation point character (!).

13.3.5.2. UDP Protocol

These match options are available for the UDP protocol (`-p udp`):

- `--dport` — Specifies the destination port of the UDP packet, using the service name, port number, or range of port numbers. The `--destination-port` match option may be used instead of `--dport`. See the `--dport` match option in Section 13.3.5.1 for various ways to use this option.
- `--sport` — Specifies the source port of the UDP packet, using the service name, port number, or range of port numbers. The `--source-port` match option may be used instead of `--sport`. See the `--dport` match option in Section 13.3.5.1 for various ways to use this option.

13.3.5.3. ICMP Protocol

Packets using the Internet Control Message Protocol (ICMP) can be matched using the following option when `-p icmp` is specified:

- `--icmp-type` — Sets the name or number of the ICMP type to match with the rule. A list of valid ICMP names can be seen by typing the `iptables -p icmp -h` command.

13.3.5.4. Modules with Additional Match Options

Additional match options are also available through modules loaded when the `iptables` command calls them. To use a match option module, you must load the module by name by including `-m <module-name>` in the `iptables` command.

A large number of modules are available by default. It is even possible to create your own modules to provide additional match option functionality. Many modules exist, but only the most popular ones are discussed here.

The `limit` module allows you to place a limit on how many packets will be matched to a particular rule. This is especially beneficial when logging rule matches so that a flood of matching packets will not fill up your logs with repetitive messages or use too many system resources.

- `--limit` — Sets the number of matches for a particular range of time, specified with a number and time modifier arranged in a `<number>/<time>` format. For example, using `--limit 5/hour` only lets a rule match five times in a single hour.

If a number and time modifier are not used, the default value of `3/hour` is assumed.

- `--limit-burst` — Sets a limit on the number of packets able to match a rule at one time. This option should be used in conjunction with the `--limit` option, and it accepts a number to set the burst threshold.

If no number is specified, only five packets are initially able to match the rule.

The `state` module, which uses the `--state` match option, can match a packet with these particular connection states:

- `ESTABLISHED` — The matching packet is associated with other packets in an established connection.

- `INVALID` — The matching packet cannot be tied to a known connection.
- `NEW` — The matching packet is either creating a new connection or is part of a two-way connection not previously seen.
- `RELATED` — The matching packet is starting a new connection related in some way to an existing connection.

These connection states can be used in combination with one another by separating them with commas, such as `-m state --state INVALID,NEW`.

To specifically match a hardware MAC address of an Ethernet device, use the `mac` module, which accepts `--mac-source` plus a MAC address as an option. To exclude a MAC address from a rule, place an exclamation point (!) after the `--mac-source` match option.

To view other match options available through modules, see the `iptables` man page.

13.3.6. Target Options

Once a packet has matched a particular rule, the rule can direct the packet to a number of different targets that decide its fate and, possibly, take additional actions, such as logging the action. Additionally, each chain has a default target, which is used if none of the rules on that chain match a packet or if none of the rules which match the packet specify a target.

There are only a few standard targets available to decide what happens with the packet:

- `<user-defined-chain>` — The name of a previously created and defined chain within this table with rules that will be checked against this packet, in addition to any other rules in any other chains that must be checked against this packet.
- `ACCEPT` — Allows the packet to successfully move on to its destination or another chain.
- `DROP` — Drops the packet without responding to the requester. The system that sent the packet is not notified of the failure. The packet is simply removed from the rule checking the chain and discarded.
- `QUEUE` — The packet is queued for handling by a user-space application.
- `RETURN` — Stops checking the packet against rules in the current chain. If the packet with a `RETURN` target matches a rule in a chain called from another chain, the packet is returned to the first chain to resume rule checking where it left off. If the `RETURN` rule is used on a built-in chain and the packet cannot move up to its previous chain, the default target for the current chain decides what action to take.

In addition to these standard targets, various other targets may be used with extensions called *target modules*. For more information about match option modules, see Section 13.3.5.4.

There are many extended target modules, most of which only apply to specific tables or situations. A couple of the most popular target modules included by default in Red Hat Linux are:

- `LOG` Logs all packets that match this rule. Since the packets are logged by the kernel, the `/etc/syslog.conf` file determines where these log entries are written. By default, they are placed in the `/var/log/messages` file.

Various options can be used after the `LOG` target to specify the way in which logging occurs:

- `--log-level` — Sets the priority level of a logging event. A list of priority levels can be found in the `syslog.conf` man page.
- `--log-ip-options` — Any options set in the header of a IP packet is logged.

- `--log-prefix` — Places a string before the log line when it is written. Accepts up to 29 characters after the `--log-prefix` option. This is useful for writing syslog filters for use in conjunction with packet logging.
 - `--log-tcp-options` — Any options set in the header of a TCP packet is logged
 - `--log-tcp-sequence` — Writes the TCP sequence number for the packet in the log.
- **REJECT** — Sends an error packet back to the system which sent the packet, and then drops the packet. This target is useful if you would like to notify the system sending the matching packet of the problem.

The **REJECT** target accepts a `--reject-with <type>` option which allows more detailed information to be sent with the error packet. The message `port-unreachable` is the default `<type>` error given if no other option is used. For a full list of `<type>` options that can be used, see the `iptables` man page.

Other target extensions, including several that are useful with masquerading using the `nat` table or with packet alteration using the `mangle` table, can be found in the `iptables` man page.

13.3.7. Listing Options

The default list command, `iptables -L`, provides a very basic overview of the default filter table's current chains. Additional options provide more information and arrange that information in specific ways:

- `-v` — Display verbose output, such as the number of packets and bytes each chain has seen, the number of packets and bytes each rule has matched, and which interfaces apply to a particular rule.
- `-x` — Expands numbers into their exact values. On a busy system, the number of packets and bytes seen by a particular chain or rule may be abbreviated using `K` (thousands), `M` (millions), and `G` (billions) at the end of the number. This option forces the full number to be displayed.
- `-n` — Displays IP addresses and port numbers in numeric format, rather than the default hostname and network service format.
- `--line-numbers` — Lists rules in each chain next to their numeric order in the chain. This option is useful when attempting to delete a specific rule in a chain, or to locate where to insert a rule within a chain.

13.4. Storing iptables Information

Rules created with the `iptables` command are stored in RAM only. If you restart your system after setting up `iptables` rules, they will be lost. So in order for netfilter rules to persist through system reboot, you need to save them to the `/etc/sysconfig/iptables` file.

To do this, type the `/sbin/service iptables save` command as the root user. This causes the `iptables` init script to run the `/sbin/iptables-save` program and write the current `iptables` configuration to the `/etc/sysconfig/iptables` file. This file should only be readable by root, so your packet filtering rules are not viewable by average users.

The next time the system boots, the `iptables` init script will reapply the rules saved in `/etc/sysconfig/iptables` by using the `/sbin/iptables-restore` command.

While it is always a good idea to test a new `iptables` rule before committing it to the `/etc/sysconfig/iptables` file, it is possible to copy `iptables` rules into this file from another

system's version of this file. This allows you to quickly distribute sets of `iptables` rules to many different machines.

Important

If you distribute the `/etc/sysconfig/iptables` file to other machines, you must type `/sbin/service iptables restart` for the new rules take effect.

13.5. Additional Resources

See the sources below for additional information on packet filtering with `iptables`.

13.5.1. Installed Documentation

- The `iptables` man page contains a comprehensive description of various commands, parameters, and other options.

13.5.2. Useful Websites

- <http://netfilter.samba.org> — Contains assorted information about `iptables`, including an FAQ addressing specific problems you may experience and various helpful guides by Rusty Russell, the Linux IP firewall maintainer. The HOWTO documents here cover subjects such as basic networking concepts, 2.4 kernel packet filtering and NAT configurations.
- http://www.linuxnewbie.org/nhf/Security/IPtables_Basics.html — A basic and general look at the way packets move through the Linux kernel, plus an introduction to constructing simple `iptables` commands.
- <http://www.redhat.com/support/resources/networking/firewall.html> — This webpage contains update-to-date links to a variety of packet filter resources.

Apache HTTP Server

The Apache HTTP Server is a robust, commercial-grade open source Web server developed by the Apache Software Foundation (<http://www.apache.org>). Red Hat Linux 8.0 includes the Apache HTTP Server version 2.0 as well as a number of server modules designed to enhance its functionality.

The default configuration file installed with the Apache HTTP Server works without alteration for most situations. This chapter, however, outlines how to customize the Apache HTTP Server configuration file (`/etc/httpd/conf/httpd.conf`) for situations where the default configuration does not suit your needs.

Warning

If you plan to use the graphical **HTTP Configuration Tool** (`redhat-config-httpd`), *do not* edit the Apache HTTP Server's configuration file. The **HTTP Configuration Tool** regenerates this file whenever it is used.

If you need more information on the **HTTP Configuration Tool**, please see the chapter titled *Apache HTTP Server Configuration* in the *Official Red Hat Linux Customization Guide*.

14.1. Apache HTTP Server 2.0

Red Hat Linux 8.0 ships with version 2.0 of the Apache HTTP Server. There are important differences between version 2.0 and version 1.3 — which shipped with earlier releases of Red Hat Linux. This section reviews some of the new features of Apache HTTP Server 2.0 and outlines important changes. If you need to migrate a version 1.3 configuration file to the new format, refer to Section 14.2.

14.1.1. Features of Apache HTTP Server 2.0

The arrival of Apache HTTP Server 2.0 brings with it a number of new features. Among them are the following:

- *New Apache API* — The Apache HTTP Server has a new, more powerful set of Application Programming Interfaces (APIs) for modules.

Caution

Modules built for Apache HTTP Server 1.3 will not work without being ported to the new API. If you are unsure whether or not a particular module has been ported, consult with the package maintainer *before* upgrading.

- *Filtering* — Modules for Apache HTTP Server 2.0 have the ability to act as content filters. See Section 14.2.4 for more on how filtering works.
- *IPv6 Support* — Apache HTTP Server 2.0 supports next generation IP addressing.
- *Simplified Directives* — A number of confusing directives have been removed while others have been simplified. See Section 14.5 for more information about specific directives.
- *Multilingual Error Responses* — When using *Server Side Include (SSI)* documents, customizable error response pages can be delivered in multiple languages.
- *Multiprotocol Support* — Apache HTTP Server 2.0 has the ability to serve multiple protocols.

A more complete list complete list of changes can be found online at <http://httpd.apache.org/docs-2.0/>.

14.1.2. Packaging Changes in Apache HTTP Server 2.0

Under Red Hat Linux 8.0 the Apache HTTP Server package has been renamed. Also, some related packages have been renamed, deprecated, or incorporated into other packages.

Below is a list of the packaging changes:

- The `apache`, `apache-devel` and `apache-manual` packages have been renamed as `httpd`, `httpd-devel` and `httpd-manual` respectively.
- The `mod_dav` package has been incorporated into the `httpd` package.
- The `mod_put` and `mod_roaming` packages have been removed, since their functionality is a subset of that provided by `mod_dav`.
- The `mod_auth_any` and `mod_bandwidth` packages have been removed.
- The version number for the `mod_ssl` package is now synchronized with the `httpd` package. This means that the `mod_ssl` package for Apache HTTP Server 2.0 has a *lower* version number than `mod_ssl` package for Apache HTTP Server 1.3.

14.1.3. File System Changes in Apache HTTP Server 2.0

The following changes to the file system layout occur when upgrading to Apache HTTP Server 2.0:

- *A new configuration directory, `/etc/httpd/conf.d/`, has been added.* — This new directory is used to store configuration files for individually packaged modules, such as `mod_ssl`, `mod_perl`, and `php`. The server is instructed to load configuration files from this location by the directive `Include conf.d/*.conf` within the Apache HTTP Server configuration file, `/etc/httpd/conf/httpd.conf`.

It is vital that this line be inserted when migrating an existing configuration.

- *The `ab` and `logresolve` programs have been moved.* — These utility programs have been moved from the `/usr/sbin/` directory and into the `/usr/bin/` directory. This will cause scripts with absolute paths for these binaries to fail.
- *The `dbmmanage` command has been replaced.* — The `dbmmanage` command has been replaced by `htdbm`. See Section 14.2.4.4 for more information.
- *The `logrotate` configuration file has has been renamed.* — The `logrotate` configuration file has been renamed from `/etc/logrotate.d/apache` to `/etc/logrotate.d/httpd`.

The next section will outline how to migrate an Apache HTTP Server 1.3 configuration to the new 2.0 format.

14.2. Migrating Apache HTTP Server 1.3 Configuration Files

If you have upgraded your server from a previous version of Red Hat Linux upon which the Apache HTTP Server was already installed, then the new stock configuration file for the Apache HTTP Server 2.0 package will be installed as `/etc/httpd/conf/httpd.conf.rpmnew` and your original version 1.3 `httpd.conf` will not be touched. It is, of course, entirely up to you whether you use the new configuration file and migrate your old settings to it, or use your existing file as a base and modify

it to suit; however, some parts of the file have changed more than others and a mixed approach is generally the best. The stock configuration files for both version 1.3 and version 2.0 are divided into three sections. The goal of this guide is to suggest what is hopefully the easiest route.

If your `httpd.conf` is a modified version of the default Red Hat version and you have saved a copy of the original then you may find it easiest to invoke the `diff` command, as in the following example:

```
diff -u httpd.conf.orig httpd.conf | less
```

This command will highlight the modifications you have made. If you do not have a copy of the original file, extract it from an RPM package using the `rpm2cpio` and `cpio` commands, as in the following example:

```
rpm2cpio apache-1.3.23-11.i386.rpm | cpio -i --make
```

Finally, it is useful to know that the Apache HTTP Server has a testing mode to check your configuration for errors. To use access it, type the following command:

```
apachectl configtest
```

14.2.1. Global Environment Configuration

The global environment section of the configuration file contains directives which affect the overall operation of the Apache HTTP Server, such as the number of concurrent requests it can handle and the locations of the various files it uses. This section requires a large number of changes compared with the others and it is therefore recommended that you base this section on the Apache HTTP Server 2.0 configuration file and migrate your old settings into it.

14.2.1.1. Selecting Which Interfaces and Ports To Bind To

The `BindAddress` and `Port` directives no longer exist; their functionality is now provided by a more flexible `Listen` directive.

If you had set `Port 80` in your 1.3 version configuration file, you should change it to `Listen 80` instead. If you had set `Port` to some value *other than 80* then you must also append the port number to the contents of your `ServerName` directive.

For example, the following is a sample Apache HTTP Server 1.3 directive:

```
Port 123
ServerName www.example.com
```

To migrate this setting to Apache HTTP Server 2.0, use the following structure:

```
Listen 123
ServerName www.example.com:123
```

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mpm_common.html#listen
- <http://httpd.apache.org/docs-2.0/mod/core.html#servername>

14.2.1.2. Server-pool Size Regulation

In Apache HTTP Server 2.0, the responsibility for accepting requests and dispatching child-processes to handle them has been abstracted into a group of modules called *Multi-Processing Modules (MPMs)*. Unlike other modules, only one module from the MPM group can be loaded by the Apache HTTP Server because an MPM module is responsible for basic request handling and dispatching. There are three MPM modules that ship with version 2.0: prefork, worker, and perchild.

The original Apache HTTP Server 1.3 behavior has been moved into the prefork MPM. Currently only the prefork MPM is available on Red Hat Linux, although other MPMs may be made available at some later date.

The MPM supplied by default on Red Hat Linux is prefork which accepts the same directives as Apache HTTP Server 1.3. The following directives may be migrated directly:

- `StartServers`
- `MinSpareServers`
- `MaxSpareServers`
- `MaxClients`
- `MaxRequestsPerChild`

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- <http://httpd.apache.org/docs-2.0/mpm.html>

14.2.1.3. Dynamic Shared Object (DSO) Support

There are many changes required here and it is highly recommended that anyone trying to modify an Apache 1.3 configuration to suit Apache 2.0 (as opposed to migrating your changes into the Apache 2.0 configuration) copy this section from the stock Red Hat Linux Apache HTTP Server 2.0 configuration file.

Important

If you do decide to try and modify your original file, please note that it is of paramount importance that your `httpd.conf` contains the following directive:

```
Include conf.d/*.conf
```

Omission of this directive will result in the failure of all modules packaged in their own RPMs (such as `mod_perl`, `php`, and `mod_ssl`).

Those who still do not want to copy the section from the stock Apache HTTP Server 2.0 configuration should note the following:

- The `AddModule` and `ClearModuleList` directives no longer exist. These directives were used to ensure that modules could be enabled in the correct order. The Apache 2.0 API allows modules to specify their ordering, eliminating the need for these two directives.
- The order of the `LoadModule` lines is no longer relevant.
- Many modules have been added, removed, renamed, split up, or incorporated with each other.

- `LoadModule` lines for modules packaged in their own RPMs (`mod_ssl`, `php`, `mod_perl`, and the like) are no longer necessary as they can be found in the relevant file in the `/etc/httpd/conf.d/` directory.
- The various `HAVE_XXX` definitions are no longer defined.

14.2.1.4. Other Global Environment Changes

The following directives have been removed from Apache HTTP Server 2.0's configuration:

- `ServerType` — The Apache HTTP Server can only be run as `ServerType standalone` making this directive irrelevant.
- `AccessConfig` and `ResourceConfig` — These directives have been removed since they mirror the functionality of the `Include` directive. If you have `AccessConfig` and `ResourceConfig` directives set then you need to replace these with `Include` directives.

To ensure that the files are read in the order implied by the older directives the `Include` directives should be placed at the end of `httpd.conf`, with the one corresponding to `ResourceConfig` preceding the one corresponding to `AccessConfig`. If you were making use of the default values you will need to include them explicitly as `conf/srm.conf` and `conf/access.conf`.

14.2.2. Main Server Configuration

The main server configuration section of the configuration file sets up the main server, which responds to any requests that are not handled by a `<VirtualHost>` definition. Values here also provide defaults for any `<VirtualHost>` containers you may define.

The directives used in this section have changed little between Apache HTTP Server 1.3 and version 2.0. If your main server configuration is heavily customized you may find it easier to modify your existing configuration to suit Apache 2.0. Users with only lightly customized main server sections should migrate their changes into the stock Apache 2.0 configuration.

14.2.2.1. UserDir Mapping

The `UserDir` directive is used to enable URLs such as `http://example.com/~jim/` to map to a subdirectory within the home directory of the user `jim`, such as `/home/jim/public_html`. A side-effect of this feature allows a potential attacker to determine whether a given username is present on the system, so the default configuration for Apache HTTP Server 2.0 disables this directive.

To enable `UserDir` mapping, change the directive in `httpd.conf` from:

```
UserDir disable
```

to the following:

```
UserDir public_html
```

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_userdir.html#userdir

14.2.2.2. Logging

The following logging directives have been removed:

- `AgentLog`
- `RefererLog`
- `RefererIgnore`

However, agent and referrer logs are still available using the `CustomLog` and `LogFormat` directives.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_log_config.html#customlog
- http://httpd.apache.org/docs-2.0/mod/mod_log_config.html#logformat

14.2.2.3. Directory Indexing

The deprecated `FancyIndexing` directive has now been removed. The same functionality is available through the `FancyIndexing` *option* within the `IndexOptions` directive.

The new `VersionSort` option to the `IndexOptions` directive causes files containing version numbers to be sorted in the natural way, so that `httpd-2.0.6.tar` would appear before `httpd-2.0.36.tar` in a directory index page.

The defaults for the `ReadmeName` and `HeaderName` directives have changed from `README` and `HEADER` to `README.html` and `HEADER.html`.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_autoindex.html#indexoptions
- http://httpd.apache.org/docs-2.0/mod/mod_autoindex.html#readmename
- http://httpd.apache.org/docs-2.0/mod/mod_autoindex.html#headername

14.2.2.4. Content Negotiation

The `CacheNegotiatedDocs` directive now takes the argument `on` or `off`. Existing instances of `CacheNegotiatedDocs` should be replaced with `CacheNegotiatedDocs on`.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_negotiation.html#cachenegotiateddocs

14.2.2.5. Error Documents

To use a hard-coded message with the `ErrorDocument` directive, the message should be enclosed in a pair of double quotes, rather than just preceded by a double quote as required in Apache 1.3.

To migrate an `ErrorDocument` setting to Apache HTTP Server 2.0, use the following structure:

```
ErrorDocument 404 "The document was not found"
```

Note that there is a trailing double quote in the example `ErrorDocument` directive above.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- <http://httpd.apache.org/docs-2.0/mod/core.html#errorocument>

14.2.3. Virtual Hosts Configuration

The contents of all `<VirtualHost>` containers should be migrated in the same way as the main server section as described in Section 14.2.2.

Important

Note that SSL/TLS virtual host configuration has been moved out of the main server configuration file and into `/etc/httpd/conf.d/ssl.conf`.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- <http://httpd.apache.org/docs-2.0/vhosts/>

14.2.4. Modules and Apache HTTP Server 2.0

In Apache HTTP Server 2.0, the module system has been changed to allow modules to be chained together or combined in new and interesting ways. CGI scripts, for example, can generate server-parsed HTML documents which can then be processed by `mod_include`. This opens up a tremendous number of possibilities with regards to how modules can be combined to achieve a specific goal.

The way this works is that each request is served by exactly one *handler* module followed by zero or more *filter* modules.

Under Apache 1.3, for example, a PHP script would be handled in its entirety by the PHP module. Under Apache 2.0, the request is initially *handled* by the core module — which serves static files — and is then *filtered* by the PHP module.

Exactly how to use this and all the other new features of Apache 2.0 for that matter is beyond the scope of this document; however, the change has ramifications if you have used `PATH_INFO`, which contains trailing path information after the true filename, in a document which is handled by a module that is now implemented as a filter. The core module, which initially handles the request, does not by default understand `PATH_INFO` and will return 404 Not Found errors for requests that contain such information. You can use the `AcceptPathInfo` directive to coerce the core module into accepting requests with `PATH_INFO`. Below is an example of this directive:

```
AcceptPathInfo on
```

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- <http://httpd.apache.org/docs-2.0/mod/core.html#acceptpathinfo>
- <http://httpd.apache.org/docs-2.0/handler.html>
- <http://httpd.apache.org/docs-2.0/filter.html>

14.2.4.1. The `mod_ssl` Module

The configuration for `mod_ssl` has been moved from `httpd.conf` into the file `/etc/httpd/conf.d/ssl.conf`. For this file to be loaded, and hence for `mod_ssl` to work, you must have the statement `Include conf.d/*.conf` in your `httpd.conf` as described in Section 14.2.1.3.

`ServerName` directives in SSL virtual hosts must explicitly specify the port number.

For example, the following is a sample Apache HTTP Server 1.3 directive:

```
##
## SSL Virtual Host Context
##

<VirtualHost _default_:443>
    # General setup for the virtual host
    ServerName ssl.host.name
    ...
</VirtualHost>
```

To migrate this setting to Apache HTTP Server 2.0, use the following structure:

```
##
## SSL Virtual Host Context
##

<VirtualHost _default_:443>
    # General setup for the virtual host
    ServerName ssl.host.name:443
    ...
</VirtualHost>
```

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_ssl.html
- <http://httpd.apache.org/docs-2.0/vhosts/>

14.2.4.2. The `mod_proxy` Module

Proxy access control statements are now placed inside a `<Proxy>` block rather than a `<Directory proxy:>`.

The caching functionality of the old `mod_proxy` has been split out into the following three modules:

- `mod_cache`
- `mod_disk_cache`
- `mod_file_cache`

These generally use the same or similar directives as the older versions of the `mod_proxy` module.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_proxy.html

14.2.4.3. The `mod_include` Module

The `mod_include` module is now implemented as a filter (see Section 14.2.4 for more on filters) and is therefore enabled differently.

For example, the following is a sample Apache HTTP Server 1.3 directive:

```
AddType text/html .shtml
AddHandler server-parsed .shtml
```

To migrate this setting to Apache HTTP Server 2.0, use the following structure:

```
AddType text/html .shtml
AddOutputFilter INCLUDES .shtml
```

Note that just as before, the `Options +Includes` directive is still required for the `<Directory>` section or in a `.htaccess` file.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_include.html

14.2.4.4. The `mod_auth_dbm` and `mod_auth_db` Modules

Apache HTTP Server 1.3 supported two authentication modules, `mod_auth_db` and `mod_auth_dbm`, which used Berkeley Databases and DBM databases respectively. These modules have been combined into a single module named `mod_auth_dbm` in Apache HTTP Server 2.0, which can access several different database formats. To migrate from `mod_auth_db` in version 1.3, configuration files should be adjusted by replacing `AuthDBUserFile` and `AuthDBGroupFile` with the `mod_auth_dbm` equivalents: `AuthDBMUserFile` and `AuthDBMGroupFile`. Also, you must add the directive `AuthDBMType DB` to indicate the type of database file in use.

The following example shows a sample `mod_auth_db` configuration for Apache 1.3:

```
<Location /private/>
  AuthType Basic
  AuthName "My Private Files"
  AuthDBUserFile /var/www/authdb
  require valid-user
</Location>
```

To migrate this setting to version 2.0 of Apache HTTP Server, use the following structure:

```
<Location /private/>
  AuthType Basic
  AuthName "My Private Files"
  AuthDBMUserFile /var/www/authdb
  AuthDBMType DB
  require valid-user
</Location>
```

Note that the `AuthDBMUserFile` directive can also be used in `.htaccess` files.

The `dbmmanage` Perl script, used to manipulate username and password databases, has been replaced by `htdbm` in Apache HTTP Server 2.0. The `htdbm` program offers equivalent functionality and like `mod_auth_dbm` can operate a variety of database formats; the `-T` option can be used on the command line to specify the format to use.

Table 14-1 shows how to migrate from a DBM-format database to `htdbm` format using `dbmmanage`.

Action	dbmmanage command (Apache 1.3)	Equivalent htdbm command (Apache 2.0)
Add user to database (using given password)	dbmmanage authdb add username password	htdbm -b -TDB authdb username password
Add user to database (prompts for password)	dbmmanage authdb adduser username	htdbm -TDB authdb username
Remove user from database	dbmmanage authdb delete username	htdbm -x -TDB authdb username
List users in database	dbmmanage authdb view	htdbm -l -TDB authdb
Verify a password	dbmmanage authdb check username	htdbm -v -TDB authdb username

Table 14-1. Migrating from dbmmanage to htdbm

The `-m` and `-s` options work with both `dbmmanage` and `htdbm`, enabling the use of the MD5 or SHA1 algorithms for hashing passwords, respectively.

When creating a new database with `htdbm`, the `-c` option must be used.

For more on this topic, refer to the following documentation on the Apache Software Foundation's website:

- http://httpd.apache.org/docs-2.0/mod/mod_auth_dbm.html

14.2.4.5. The mod_perl Module

The configuration for `mod_perl` has been moved from `httpd.conf` into the file `/etc/httpd/conf.d/perl.conf`. For this file to be loaded, and hence for `mod_perl` to work, you must have the statement `Include conf.d/*.conf` in your `httpd.conf` as described in Section 14.2.1.3.

Occurrences of `Apache::` in your `httpd.conf` must be replaced with `ModPerl::`. Additionally, the manner in which handlers are registered has been changed.

This is a sample Apache HTTP Server 1.3 `mod_perl` configuration:

```
<Directory /var/www/perl>
  SetHandler perl-script
  PerlHandler Apache::Registry
  Options +ExecCGI
</Directory>
```

This is the equivalent `mod_perl` for Apache HTTP Server 2.0:

```
<Directory /var/www/perl>
  SetHandler perl-script
  PerlModule ModPerl::Registry
  PerlHandler ModPerl::Registry::handler
  Options +ExecCGI
</Directory>
```

Most modules for `mod_perl 1.x` should work without modification with `mod_perl 2.x`. XS modules will require recompilation and may possibly require minor Makefile modifications.

14.2.4.6. The `mod_python` Module

The configuration for `mod_python`; has been moved from `httpd.conf` into the file `/etc/httpd/conf.d/python.conf`. For this file to be loaded, and hence for `mod_python`; to work, you must have the statement `Include conf.d/*.conf` in your `httpd.conf` as described in Section 14.2.1.3.

14.2.4.7. PHP

The configuration for PHP has been moved from `httpd.conf` into the file `/etc/httpd/conf.d/php.conf`. For this file to be loaded, you must have the statement `Include conf.d/*.conf` in your `httpd.conf` as described in Section 14.2.1.3.

The PHP is now implemented as a filter and must therefore be enabled in a different manor. See Section 14.2.4 for more about filters.

Under Apache HTTP Server 1.3, PHP was implemented using the following directives:

```
AddType application/x-httpd-php .php
AddType application/x-httpd-php-source .phps
```

Under Apache HTTP Server 2.0, use the following directives instead:

```
<Files *.php>
    SetOutputFilter PHP
    SetInputFilter PHP
</Files>
```

In PHP 4.2.0 and later the default set of predefined variables which are available in the global scope has changed. Individual input and server variables are, by default, no longer placed directly into the global scope. This change may cause scripts to break. You may revert to the old behavior by setting `register_globals` to `On` in the file `/etc/php.ini`.

For more on this topic, refer to the following URL for details concerning the global scope changes:

- http://www.php.net/release_4_1_0.php

14.3. After Installation

After you have installed the `httpd` package, the Apache HTTP Server's documentation is available by installing the `httpd-manual` package and pointing a Web browser to `http://localhost/manual/` or you can browse the Apache documentation available on the Web at `http://httpd.apache.org/docs-2.0/`.

The Apache HTTP Server's documentation contains a full list and complete descriptions of all configuration options. For your convenience, this chapter provides short descriptions of the configuration directives used by Apache HTTP Server 2.0.

The version of the Apache HTTP Server included with Red Hat Linux includes the ability to set up secure Web servers using the strong SSL encryption provided by the `mod_ssl` and `openssl` packages. As you look through the configuration files, be aware that it includes both a non-secure and a secure Web server. The secure Web server runs as a virtual host, which is configured in the `/etc/httpd/conf.d/ssl.conf` file. For more information about virtual hosts, see Section 14.8. For information on configuring a secure server virtual host, Section 14.8.2. For information on setting up an Apache HTTP Secure Server see the chapter titled *Apache HTTP Secure Server Configuration* in the *Official Red Hat Linux Customization Guide*.

**Note**

Red Hat, Inc. does not ship FrontPage extensions as the Microsoft™ license prohibits the inclusion of these extensions in a third party product. To find out more about FrontPage extensions and the Apache HTTP Server, refer to <http://www.rtr.com/fpsupport/>.

14.4. Starting and Stopping `httpd`

The `httpd` RPM installs the `/etc/rc.d/init.d/httpd` Bourne script, which is accessed using the `/sbin/service` command.

To start your server, as root type:

```
/sbin/service httpd start
```

**Note**

If you are running the Apache HTTP Server as a secure server, you will be prompted to type your password.

To stop your server, type the command:

```
/sbin/service httpd stop
```

The command `restart` is a shorthand way of stopping and then starting your server. The `restart` command explicitly stops and then starts your server. You will be prompted for your password if you are running the Apache HTTP Server as a secure server. The `restart` command looks like the following:

```
/sbin/service httpd restart
```

If you just finished editing something in your `httpd.conf` file, you do not need to explicitly stop and start your server. Instead, you can use the `reload` command.

**Note**

If you are running the Apache HTTP Server as a secure server, you will *not* need to type your password when using the `reload` option as the password will remain cached across reloads.

The `reload` command looks like the following example:

```
/sbin/service httpd reload
```

By default, the `httpd` process will *not* start automatically when your machine boots. You will need to configure the `httpd` service to start up at boot time using an initscript utility, such as `/sbin/chkconfig`, `/sbin/ntsysv`, or the **Services Configuration Tool** program.

Please refer to the chapter titled *Controlling Access to Services* in *Official Red Hat Linux Customization Guide* for more information regarding these tools.

**Note**

If you are running the Apache HTTP Server as a secure server, you will be prompted for the secure server's password after the machine boots, unless you generated a specific type of server key file.

For information about setting up an Apache HTTP Secure Server see the chapter titled *Apache HTTP Secure Server Configuration* in the *Official Red Hat Linux Customization Guide*.

14.5. Configuration Directives in `httpd.conf`

The Apache HTTP Server configuration file is `/etc/httpd/conf/httpd.conf`. The `httpd.conf` file is well-commented and mostly self-explanatory. Its default configuration will work for most situations, however you should become familiar some of the more important configuration options.

**Warning**

With the release of Apache HTTP Server 2.0, many configuration options have changed. If you need to migrate a version 1.3 configuration file to the new format, refer to Section 14.2.

If you need to configure the Apache HTTP Server, edit `httpd.conf` and then either reload, restart, or stop and start the `httpd` process. How to reload, stop and start the Apache HTTP Server is covered in Section 14.4.

Before you edit `httpd.conf`, you should first copy the original file to something like `httpd.conf-old`, for example. By creating a backup, you can recover potential mistakes made while editing the new configuration file.

If you do make a mistake and your Web server does not work correctly, first review what you have recently edited in `httpd.conf`. Make sure there are no typos.

Next look in the Web server's error log (`/var/log/httpd/error_log`). The error log may not be easy to interpret, depending on your level of experience. If you have just experienced a problem, however, the last entries in the error log should provide information about what happened.

The next sections provide short descriptions of the directives included in `httpd.conf`. These descriptions are not exhaustive. If you need more information, refer to the Apache documentation provided in HTML format at <http://localhost/manual/> or the Apache group documentation at <http://httpd.apache.org/docs-2.0/>.

For more information about `mod_ssl` directives, refer to the documentation included in HTML format at http://localhost/mod/mod_ssl.html or the Apache group `mod_ssl` documentation at http://httpd.apache.org/docs-2.0/mod/mod_ssl.html.

14.5.1. ServerRoot

The `ServerRoot` is the top-level directory which contains the server's files. Both your secure and non-secure servers are set to use a `ServerRoot` of `"/etc/httpd"`.

14.5.2. LockFile

`LockFile` sets the path to the lockfile used when `httpd` is compiled with either `USE_FCNTL_SERIALIZED_ACCEPT` or `USE_FLOCK_SERIALIZED_ACCEPT`. `LockFile` should be left at its default value.

14.5.3. PidFile

`PidFile` names the file where the server records its process ID (pid). Your Web server is set to record its pid in `/var/run/httpd.pid`.

14.5.4. ScoreBoardFile

The `ScoreBoardFile` stores internal server process information, which is used for communication between the parent server process and its child processes. Red Hat Linux uses shared memory to store the `ScoreBoardFile`, the default of `/etc/httpd/logs/apache_runtime_status` is only used as a fallback.

14.5.5. Timeout

`Timeout` defines, in seconds, the amount of time that your server will wait for receipts and transmissions during communications. Specifically, `Timeout` defines how long your server will wait to receive a GET request, how long it will wait to receive TCP packets on a POST or PUT request and how long it will wait between ACKs responding to TCP packets. `Timeout` is set to 300 seconds, which is appropriate for most situations.

14.5.6. KeepAlive

`KeepAlive` sets whether your server will allow more than one request per connection (in other words, it will allow persistent connections). `KeepAlive` can be used to prevent any one client from consuming too much of the server's resources.

By default `Keepalive` is set to off. If `Keepalive` is set to on and the server becomes very busy, the server can quickly spawn the maximum number of child processes. In this situation, the server will slow down significantly. If `Keepalive` is enabled, it is a good idea to set the `KeepAliveTimeout` low (see Section 14.5.8) and monitor the servers `/var/log/httpd/error_log`. This log will report when the server is running out of child processes.

14.5.7. MaxKeepAliveRequests

This directive sets the maximum number of requests allowed per persistent connection. The Apache Group recommends a high setting, which will improve your server's performance. `MaxKeepAliveRequests` is set to 100 by default, which should be appropriate for most situations.

14.5.8. KeepAliveTimeout

`KeepAliveTimeout` sets the number of seconds your server will wait after a request has been served before it closes the connection. Once the server receives a request, the `Timeout` directive applies instead.

14.5.9. MinSpareServers and MaxSpareServers

The Apache HTTP Server dynamically adapts to the perceived load by maintaining an appropriate number of spare server processes based on the traffic. The server checks the number of servers waiting for a request and kills some if there are more than `MaxSpareServers` or creates some if the number of servers is less than `MinSpareServers`.

Your server's default `MinSpareServers` is 5; your server's default `MaxSpareServers` is 20. These default settings should be appropriate in most situations. You should not increase the `MinSpareServers` to a large number. Doing so will create a heavy processing load on your server even when traffic is light.

14.5.10. StartServers

`StartServers` sets how many server processes are created upon startup. Since your Web server dynamically kills and creates server processes based on traffic load, you will not need to change this parameter. Your Web server is set to start eight server processes at startup.

14.5.11. MaxClients

`MaxClients` sets a limit on the total number of server processes, or simultaneously connected clients, that can run at one time. You should keep `MaxClients` at a high number (your server's default is set to 150), because no one else will be allowed to connect once that number of simultaneously connected clients is reached. You can not set `MaxClients` to higher than 256 without recompiling Apache. The main reason for having `MaxClients` is to keep a runaway Web server from crashing your operating system.

14.5.12. MaxRequestsPerChild

`MaxRequestsPerChild` sets the total number of requests each child server process serves before the child dies. The main reason for setting `MaxRequestsPerChild` is to avoid long-lived process induced memory leaks. The default `MaxRequestsPerChild` for your server is 1000.

14.5.13. Listen

The `Listen` command identifies the ports on which your Web server will accept incoming requests. Your Web server is set to listen to port 80 for non-secure Web communications and (in the virtual host tags that define the secure server) to port 443 for secure Web communications.

If you set the Apache HTTP Server to listen to a port under 1024, you must be root to start it. For port 1024 and above, `httpd` can be started as a regular user.

`Listen` can also be used to specify particular IP addresses over which the server will accept connections.

14.5.14. Include

`Include` allows other configuration files to be included at runtime.

The path to these configuration files can be absolute or relative to the `ServerRoot`.

Important

In order for the server to use individually packaged modules, such as `mod_ssl`, `mod_perl`, and `php`, the following directive must be in Section 1: Global Environment of `http.conf`:

```
Include conf.d/*.conf
```

14.5.15. LoadModule

`LoadModule` is used to load in Dynamic Shared Object (DSO) modules. More information on the Apache HTTP Server's DSO support, including exactly how to use the `LoadModule` directive, can be found in Section 14.7. Note, the load order of the modules is *no longer important* with Apache HTTP Server 2.0. See Section 14.2.1.3 for more information about Apache HTTP Server 2.0 DSO support.

14.5.16. IfDefine

The `<IfDefine>` and `</IfDefine>` tags surround configuration directives that are applied if the "test" stated in the `<IfDefine>` tag is true. The directives are ignored if the test is false.

The test in the `<IfDefine>` tags is a parameter name (for example, `HAVE_PERL`). If the parameter is defined, meaning that it is provided as an argument to the server's start-up command, then the test is true. In this case, when your Web server is started, the test is true and the directives contained in the `IfDefine` tags are applied.

By default, `<IfDefine HAVE_SSL>` tags surround the virtual host tags for your secure server. `<IfDefine HAVE_SSL>` tags also surround the `LoadModule` and `AddModule` directives for the `ssl_module`.

14.5.17. ExtendedStatus

The `ExtendedStatus` directives controls whether Apache generates basic (`off`) or detailed server status information (`on`), when the `server-status` handler is called. `Server-status` is called using `Location` tags. More information on calling `server-status` is included in Section 14.5.65.

14.5.18. User

The `User` directive sets the userid used by the server to answer requests. `User`'s setting determines the server's access. Any files inaccessible to this user will also be inaccessible to your website's visitors. The default for `User` is `apache`.

The `User` should only have privileges so that it can access files which are supposed to be visible to the outside world. The `User` is also the owner of any CGI processes spawned by the server. The `User` should not be allowed to execute any code which is not intended to be in response to HTTP requests.

Note

For security reasons, the Apache HTTP Server will refuse to run as `User root`. Using `root` as the `User` will create large security holes for your Web server.

The parent `httpd` process first runs as `root` during normal operations but is then immediately handed off to the `apache` user. The server must start as `root` because it needs to bind to a port below 1024 (the default port for secure Web communications is port 443; the default port for non-secure Web communications is port 80). Ports below 1024 are reserved for system use, so they can not be used by anyone but `root`. Once the server has attached itself to its port, however, it hands the process off to the `User` before it accepts any connection requests.

14.5.19. Group

The `Group` directive is similar to the `User`. The `Group` sets the group under which the server will answer requests. The default `Group` is `apache`.

14.5.20. ServerAdmin

`ServerAdmin` should be the email address of the Web server's administrator. This email address will show up in error messages on server-generated webpages, so users can report a problem by sending email to the server administrator. `ServerAdmin` is set by default to `root@localhost`.

Typically, a good way to set up `ServerAdmin` is to set it to `webmaster@your_domain.com`. Then alias `webmaster` to the person responsible for the Web server in `/etc/aliases`. Finally, run `/usr/bin/newaliases` to add the new alias.

14.5.21. ServerName

Use `ServerName` to set a hostname and port number (matching the `Listen` directive) for the server. The `ServerName` does not need to match the machine's actual hostname. For example, you might want to use `www.your_domain.com` when your server's real name is actually `foo.your_domain.com`. Note that the `ServerName` must be a valid Domain Name Service (DNS) name that you have the right to use — do not just make something up. For example:

```
ServerName www.your_domain.com:80
```

If you do specify a `ServerName`, be sure its IP address and server name pair are included in your `/etc/hosts` file.

14.5.22. DocumentRoot

The `DocumentRoot` is the directory which contains most of the HTML files which will be served in response to requests. The default `DocumentRoot` for both the non-secure and secure Web servers is the `/var/www/html` directory. For example, the server might receive a request for the following document:

```
http://your_domain/foo.html
```

The server will look for the following file in the default directory:

```
/var/www/html/foo.html
```

If you want to change the `DocumentRoot` so that it is not shared by the secure and the non-secure Web servers, see Section 14.8.

14.5.23. Directory

`<Directory /path/to/directory>` and `</Directory>` tags are used to enclose a group of configuration directives that are meant to apply only to that directory and all of its subdirectories. Any directive which is applicable to a directory may be used within `<Directory>` tags. `<File>` tags can be used in the same way, to apply to a specific file or files.

By default, very restrictive parameters are applied to the root directory, using the `Options` (see Section 14.5.24) and `AllowOverride` (see Section 14.5.25) directives. Under this configuration, any directory on your system which needs more permissive settings has to be explicitly given those settings.

Using `Directory` tags, the `DocumentRoot` is defined to have less rigid parameters, so that HTTP requests can be served from it.

The `cgi-bin` directory is set up to allow the execution of CGI scripts, with the `ExecCGI` option. If you need to execute a CGI script in another directory, you will need to set `ExecCGI` for that directory. For example, if your `cgi-bin` is `/var/www/cgi-bin`, but you want to execute CGI scripts from within `/home/my_cgi_directory`, add an `ExecCGI` directive to a set of `Directory` directives like the following to your `httpd.conf` file:

```
<Directory /home/my_cgi_directory>
    Options +ExecCGI
</Directory>
```

To allow CGI script execution in `/home/my_cgi_directory`, you will need to take a few extra steps besides setting `ExecCGI`. You will also need to have the `AddHandler` directive uncommented to identify files with the `.cgi` extension as CGI scripts. See Section 14.5.59 for instructions on setting `AddHandler`. Permissions for CGI scripts, and the entire path to the scripts, must be set to 0755.

14.5.24. Options

The `Options` directive controls which server features are available in a particular directory. For example, under the restrictive parameters specified for the root directory, `Options` is set to only `FollowSymLinks`. No features are enabled, except that the server is allowed to follow symbolic links in the root directory.

By default, in your `DocumentRoot` directory, `Options` is set to include `Indexes`, `Includes` and `FollowSymLinks`. `Indexes` permits the server to generate a directory listing for a directory if no `DirectoryIndex` (for example, `index.html`) is specified. `Includes` means that server-side includes are permitted. `FollowSymLinks` allows the server to follow symbolic links in that directory.

You will also need to include `Options` statements for directories within virtual hosts directives, if you want your virtual hosts to recognize those `Options`.

For example, server side includes are already enabled inside the `/var/www/html` directory, because of the `Options Includes` line within the `<Directory "/var/www/html">` directives section. However, if you want a virtual host to recognize server side includes, you will need to include a section like the following within your virtual host's tags:

```
<Directory /var/www/html>
Options Includes
</Directory>
```

14.5.25. AllowOverride

The `AllowOverride` directive sets whether or not any `Options` can be overridden by the declarations in an `.htaccess` file. By default, both the root directory and the `DocumentRoot` are set to allow no `.htaccess` overrides.

14.5.26. Order

The `Order` directive simply controls the order in which `allow` and `deny` directives are evaluated. Your server is configured to evaluate the `Allow` directives before the `Deny` directives for your `DocumentRoot` directory.

14.5.27. Allow

`Allow` specifies which requester can access a given directory. The requester can be `all`, a domain name, an IP address, a partial IP address, a network/netmask pair, and so on. Your `DocumentRoot` directory is configured to `Allow` requests from `all` meaning everyone has access.

14.5.28. Deny

`Deny` works just like `Allow`, but you are specifying who is denied access. Your `DocumentRoot` is not configured to `Deny` requests from anyone by default.

14.5.29. UserDir

`UserDir` is the name of the subdirectory within each user's home directory where they should place personal HTML files which are to be served by the Web server.

By default, the subdirectory is `public_html`. For example, the server might receive the following request:

```
http://your_domain/~username/foo.html
```

The server would look for the file:

```
/home/username/public_html/foo.html
```

In the above example, `/home/username/` is the user's home directory (note that the default path to users' home directories may be different on your system).

Make sure that the permissions on the users' home directories are set correctly. Users' home directories must be set to `0711`. The read (`r`) and execute (`x`) bits must be set on the users' `public_html` directories (`0755` will also work). Files that will be served in users' `public_html` directories must be set to at least `0644`.

This directive is set to `disable` by default.

14.5.30. DirectoryIndex

The `DirectoryIndex` is the default page served by the server when a user requests an index of a directory by specifying a forward slash (`/`) at the end of the directory name.

When a user requests the page `http://your_domain/this_directory/`, they will get either the `DirectoryIndex` page if it exists, or a server-generated directory list. The default for `DirectoryIndex` is `index.html index.htm index.shtml index.php index.php4 index.php3 index.cgi`. The server will try to find any one of these files, and will return the first one it finds. If it does not find any of these files and `Options Indexes` is set for that directory, the server will generate and return a listing, in HTML format, of the subdirectories and files in the directory.

14.5.31. AccessFileName

`AccessFileName` names the file which the server should use for access control information in each directory. By default, your Web server is set to use `.htaccess`, if it exists, for access control information in each directory.

Immediately after the `AccessFileName` directive, a set of `Files` tags apply access control to any file beginning with a `.ht`. These directives deny Web access to any `.htaccess` files (or other files which begin with `.ht`) for security reasons.

14.5.32. CacheNegotiatedDocs

By default, your Web server asks proxy servers not to cache any documents which were negotiated on the basis of content (that is, they may change over time or because of the input from the requester). If you set `CacheNegotiatedDocs` to `on`, you are disabling that function and proxy servers will be allowed to cache documents.

14.5.33. UseCanonicalName

`UseCanonicalName` is set by default to `on`. `UseCanonicalName` allows the server to construct an URL that references itself, using `ServerName` and `Port`. When the server refers to itself in response to requests from clients, it uses this URL. If you set `UseCanonicalName` to `off`, the server will instead use the value that came in the request from the client to refer to itself.

14.5.34. TypesConfig

`TypesConfig` names the file which sets the default list of MIME type mappings (filename extensions to content types). The default `TypesConfig` file is `/etc/mime.types`. Instead of editing `/etc/mime.types`, the recommended way to add MIME type mappings is to use the `AddType` directive.

For more information about `AddType`, refer to Section 14.5.58.

14.5.35. DefaultType

`DefaultType` sets a default content type for the Web server to use for documents whose MIME types can not be determined. Your Web server defaults to assume a plain text content type for any file with an indeterminate content type.

14.5.36. IfModule

`<IfModule>` and `</IfModule>` tags surround directives that are conditional. The directives contained within the `IfModule` tags are processed under one of two conditions. The directives are processed if the module contained within the starting `<IfModule>` tag is loaded in to `httpd`. Or, if an `!` (an exclamation point) is included before the module name, the directives are processed only if the module in the starting `<IfModule>` tag is *not* compiled in.

The `mod_mime_magic.c` file is included in these `IfModule` tags. The `mod_mime_magic` module can be compared to the UNIX `file` command, which looks at a few bytes of a file's contents, then uses "magic numbers" and other hints in order to figure out the MIME type of the file.

If the `mod_mime_magic` module is compiled in to the Apache HTTP Server, these `IfModule` tags tell the `mod_mime_magic` module where the hints definition file is: `/usr/share/magic` in this case.

The `mod_mime_magic` module is not compiled in by default. If you would like to use it, see Section 14.7, for instructions on how to add modules to your server.

14.5.37. HostnameLookups

`HostnameLookups` can be set to `on`, `off` or `double`. If you allow `HostnameLookups` (by setting it to `on`), your server will automatically resolve the IP address for each connection which requests a document from your Web server. Resolving the IP address means that your server will make one or more connections to the DNS in order to find out the hostname that corresponds to a particular IP address. If you set `HostnameLookups` to `double`, your server will perform a double-reverse DNS. In

other words, after a reverse lookup is performed, a forward lookup is performed on the result. At least one of the IP addresses in the forward lookup must match the address from the first reverse lookup.

Generally, you should leave `HostnameLookups` set to `off`, because the DNS requests add a load to your server and may slow it down. If your server is busy, the effects of `HostnameLookups` will be noticeable.

`HostnameLookups` are also an issue for the Internet as a whole. All of the individual connections made to look up each hostname add up. Therefore, for your own Web server's benefit, as well as for the good of the Internet as a whole, you should leave `HostnameLookups` set to `off`.

If you like to see the hostnames in your log files, consider running one of the many log analyzer tools that perform the DNS lookups more efficiently and in bulk when you come to rotate your log files.

14.5.38. ErrorLog

`ErrorLog` names the file where server errors are logged. As this directive indicates, the error log file for your Web server is `/var/log/httpd/error_log`.

The error log is a good place to look if your Web server generates any errors or fails, and you are not sure what happened.

14.5.39. LogLevel

`LogLevel` sets how verbose the error messages in the error logs will be. `LogLevel` can be set (from least verbose to most verbose) to `emerg`, `alert`, `crit`, `error`, `warn`, `notice`, `info` or `debug`. The default `LogLevel` is `warn`.

14.5.40. LogFormat

The `LogFormat` directives in your `httpd.conf` file set up a format for the messages in your access log. The actual `LogFormat` used will depend on the settings given in the `CustomLog` directive (see Section 14.5.41).

14.5.41. CustomLog

`CustomLog` identifies the log file and the log file format. In your Web server's default configuration, `CustomLog` defines the log file in which accesses to your Web server are recorded: `/var/log/httpd/access_log`. You will need to know the location of this file if you want to generate any access-based server performance statistics for your Web server.

`CustomLog` also sets the log file format to `combined`. The common logfile format looks like this:

```
remotehost rfc931 authuser [date] "request" status bytes referer user-agent
```

```
remotehost
```

The remote hostname. If the hostname is not available from DNS, or if `HostnameLookups` is set to `Off`, then `remotehost` will be the IP address of the remote host.

```
rfc931
```

Not used. You will see a `-` in the log file in its place.

authuser

If authentication was required, this is the username with which the user identified herself. Usually, this is not used, so you will see a - in its place.

[date]

The date and time of the request.

"request"

The request string exactly as it came from the browser or client.

status

The HTTP status code which was returned to the browser or client.

bytes

The size of the document.

referer

This can give the URL of the webpage which linked to the the current request.

user-agent

This gives the name of the browser or client making the request.

14.5.42. ServerSignature

The `ServerSignature` directive adds a line containing the Apache server version and the `ServerName` of the serving host to any server-generated documents (for example, error messages sent back to clients). `ServerSignature` is set to `on` by default. You can change it to `off`, so no signature line will be added, or you can change it to `EMail`. `EMail` will add a `mailto:ServerAdmin` HTML tag to the signature line.

14.5.43. Alias

The `Alias` setting allows directories to be outside the `DocumentRoot` directory and yet still accessible to the Web server. Any URL ending in the alias will automatically resolve to the alias' path. By default, one alias is already set up. An `icons` directory can be accessed by the Web server, but the directory is not in the `DocumentRoot`. The `icons` directory, an alias, is actually `/var/www/icons/`, not `/var/www/html/icons/`.

14.5.44. ScriptAlias

The `ScriptAlias` setting defines where CGI scripts (or other types of scripts) can be found. Generally, you do not want to leave CGI scripts within the `DocumentRoot`. If CGI scripts are in `DocumentRoot`, they could potentially be viewed as text documents. Even if you do not care if people can see and then use your CGI scripts, revealing how they work creates opportunities for unscrupulous people to exploit any security holes in the script and may create a security risk for your server. By default, the `cgi-bin` directory is a `ScriptAlias` of `/cgi-bin/` and is actually located in `/var/www/cgi-bin/`.

Your `/var/www/cgi-bin` directory has `Options ExecCGI` set, meaning that execution of CGI scripts is permitted within that directory.

See Section 14.5.59 and Section 14.5.23 for instructions on how to execute CGI scripts in directories other than the `cgi-bin`.

14.5.45. Redirect

When a webpage is moved, `Redirect` can be used to map the old URL to a new URL. The format is as follows:

```
Redirect /path/foo.html http://new_domain/path/foo.html
```

So, if an HTTP request is received for a page which used to be found at `http://your_domain/path/foo.html`, the server will send back the new URL (`http://new_domain/path/foo.html`) to the client, which should attempt to fetch the document from the new URL.

For more advanced Redirection you can use the `mod_rewrite` module included with the server.

14.5.46. IndexOptions

`IndexOptions` controls the appearance of server generated directing listings, by adding icons, file descriptions, and so on. If `Options Indexes` is set (see Section 14.5.24), your Web server may generate a directory listing when your Web server receives an HTTP request like the following:

```
http://your_domain/this_directory/
```

First, your Web server looks in that directory for a file from the list after the `DirectoryIndex` directive (usually, `index.html`). If your Web server does not find one of those files, it creates an HTML directory listing of the subdirectories and files in the directory. You can modify the appearance of this directory listing using certain directives in `httpd.conf`, including `IndexOptions`.

Your default configuration sets `FancyIndexing` on. If `FancyIndexing` is turned on, clicking on the column headers in the directory listing will sort the order of the display by that header. Another click on the same header will switch from ascending to descending order and back. `FancyIndexing` also shows different icons for different files, depending upon file extensions. If you use the `AddDescription` directive and turn `FancyIndexing` on, then a short description of a file will be included in the server generated directory listing.

`IndexOptions` has a number of other parameters which can be set to control the appearance of server generated directories. Parameters include `IconHeight` and `IconWidth`, to make the server include `HTML HEIGHT` and `WIDTH` tags for the icons in server generated webpages; `IconsAreLinks`, for making the icons act as part of the HTML link anchor along with the filename and others.

14.5.47. AddIconByEncoding

This directive names icons which will be displayed by files with MIME encoding, in server generated directory listings. For example, by default, your Web server shows the `compressed.gif` icon next to MIME encoded `x-compress` and `x-gzip` files in server generated directory listings.

14.5.48. AddIconByType

This directive names icons which will be displayed next to files with MIME types in server generated directory listings. For example, your server is set to show the icon `text.gif` next to files with a mime-type of "text," in server generated directory listings.

14.5.49. AddIcon

`AddIcon` tells the server which icon to show in server generated directory listings for certain file types or for files with certain extensions. For example, your Web server is set to show the icon `binary.gif` for files with `.bin` or `.exe` extensions.

14.5.50. DefaultIcon

`DefaultIcon` names the icon to show in server generated directory listings for files which have no other icon specified. The `unknown.gif` image file is the `DefaultIcon` for those files by default.

14.5.51. AddDescription

You can use `AddDescription` to show text that you specify for certain files, in server generated directory listings (you will also need to enable `FancyIndexing` as an `IndexOptions`). You can name specific files, wildcard expressions or file extensions to specify the files which this directive should apply to. For example, you could use the following line:

```
AddDescription "A file that ends in .ni" .ni
```

In server generated directory listings, all files with extensions of `.ni` would have the description `A file that ends in .ni` after the filename. Note that you will also need `FancyIndexing` turned on.

14.5.52. ReadmeName

`ReadmeName` names the file which (if it exists in the directory) will be appended to the end of server generated directory listings. The Web server will first try to include the file as an HTML document and then try to include it as plain text. By default, `ReadmeName` is set to `README`.

14.5.53. HeaderName

`HeaderName` names the file which (if it exists in the directory) will be prepended to the start of server generated directory listings. Like `ReadmeName`, the server will try to include it as an HTML document if possible, or in plain text if not.

14.5.54. IndexIgnore

`IndexIgnore` lists file extensions, partial filenames, wildcard expressions or full filenames. The Web server will not include any files which match any of those parameters in server generated directory listings.

14.5.55. AddEncoding

`AddEncoding` names filename extensions which should specify a particular encoding type. `AddEncoding` can also be used to instruct some browsers (not all) to uncompress certain files as they are downloaded.

14.5.56. AddLanguage

`AddLanguage` associates filename extensions with specific content languages. This directive is mostly useful for content negotiation, when the server returns one of several documents based on the client's language preference as set in their browser.

14.5.57. LanguagePriority

`LanguagePriority` allows you to set precedence for different languages in which to serve files, which will be in effect if the client expressed no preference for language in their browser.

14.5.58. AddType

Use the `AddType` directive to define MIME type and file extension pairs. For example, if you are using PHP4, your Web server is using the `AddType` directive to make your Web server recognize files with PHP extensions (`.php4`, `.php3`, `.phtml`, `.php`) as PHP MIME types. The following directive tells the Apache HTTP Server to recognize the `.shtml` file extension:

```
AddType text/html .shtml
AddHandler server-parsed .shtml
```

You will need to include the above line within the virtual host tags for any virtual hosts which should allow server side includes.

14.5.59. AddHandler

`AddHandler` maps file extensions to specific handlers. For example, the `cgi-script` handler can be used matched with the extension `.cgi` to automatically treat a file ending with `.cgi` as a CGI script. This will work, even for files outside of the `ScriptAlias` directory, as long as you follow the instructions provided here.

You have a CGI `AddHandler` line in your `httpd.conf` file:

```
AddHandler cgi-script .cgi
```

You will have to uncomment the line. Then Apache will execute CGI scripts for files ending in `.cgi`, even if they are outside of the `ScriptAlias`, which is set by default to locate your `/cgi-bin/` directory in `/var/www/cgi-bin/`.

You will also need to set `ExecCGI` as an `Options` for any directory containing a CGI script. See Section 14.5.23 for more information about setting `ExecCGI` for a directory. Additionally, you will need to make sure the permissions are set correctly for the CGI scripts and the directories containing CGI scripts. CGI scripts and the entire directory path to the scripts must be set to 0755.

You will need to add the same `AddHandler` line to your `VirtualHost` setup, if you are using virtual hosts and you want them to also recognize CGI scripts outside the `ScriptAlias`.

In addition to CGI scripts, your Web server also uses `AddHandler` to process server-parsed HTML and `imagemap` files.

14.5.60. Action

`Action` allows you to specify a MIME content type and CGI script pair, so that whenever a file of that media type is requested, a particular CGI script will be executed.

14.5.61. MetaDir

`MetaDir` specifies the name of a directory where your Web server should look for files containing meta information (extra HTTP headers) to include when serving documents.

14.5.62. MetaSuffix

`MetaSuffix` specifies the filename suffix for the file that contains meta information (extra HTTP headers), which should be located in the `MetaDir` directory.

14.5.63. ErrorDocument

By default, in the event of a problem or error, your Web server outputs a simple and usually cryptic error message back to the requesting client. Instead of using the default, you can use `ErrorDocument` to configure your Web server so that it outputs a customized message or redirects the client to a local or external URL. The `ErrorDocument` directive simply associates a HTTP response code with a message or a URL which will be sent back to the client.

Important

You *must* enclose the error message in a pair of double quotes for it to be valid.

14.5.64. BrowserMatch

The `BrowserMatch` directive allows your server to define environment variables and take appropriate actions based on the User-Agent HTTP header field — which identifies the client's browser. By default, your Web server uses `BrowserMatch` to deny connections to specific browsers with known problems and also to disable keepalives and HTTP header flushes for browsers that are known to have problems with those actions.

14.5.65. Location

`<Location>` and `</Location>` tags allow you to specify access control based on URL.

If you want to allow people connecting from your domain to see server status reports, you should uncomment the next section of directives:

```
#<Location /server-status>
#   SetHandler server-status
#   Order deny,allow
#   Deny from all
#   Allow from .your_domain.com
#</Location>
```

You must replace `.your_domain.com` with your second level domain name.

If you want to provide server configuration reports (including installed modules and configuration directives) to requests from inside your domain, you will need to uncomment the following lines:

```
#<Location /server-info>
#   SetHandler server-info
#   Order deny,allow
```

```
# Deny from all
# Allow from .your_domain.com
#</Location>
```

Again, you must fill in `.your_domain.com`.

14.5.66. ProxyRequests

If you uncomment the `IfModule` tags surrounding the `ProxyRequests` directives, your Apache HTTP Server will also function as a proxy server. You will also need to load the `mod_proxy` module. For instructions on how to load in modules, see Section 14.7.

14.5.67. ProxyVia

The `ProxyVia` command controls whether or not an HTTP `Via`: header line is sent along with requests or replies which go through the Apache proxy server. The `Via`: header will show the hostname if `ProxyVia` is set to `On`, the hostname and the Apache HTTP Server version for `Full`, any `Via`: lines will be passed along unchanged for `Off`, and `Via`: lines will be removed for `Block`.

14.5.68. Cache Directives

A number of cache directives are commented out in the proxy `IfModule` tags mentioned above. If you are using the proxy server functionality and you want to also enable the proxy cache, you should uncomment the cache directives as described. The default settings for your cache directives should be appropriate for most configurations.

`CacheRoot` sets the name of the directory which will contain cached files. The default `CacheRoot` is `/var/cache/httpd`.

`CacheSize` sets how much space the cache can use, in KB. The default `CacheSize` is 5 KB.

`CacheGcInterval` sets a number of hours. After that number of hours, files in the cache will be deleted if the cache is using more space than allowed by `CacheSize`. The default for `CacheGcInterval` is four hours.

Cached HTML documents will be retained (without a reload from the originating Web server) in the cache for a maximum number of hours set by `CacheMaxExpire`. The default is 24 hours.

The `CacheLastModifiedFactor` affects the creation of an expiry (expiration) date for a document which did not come from its originating server with its own expiry set. The default `CacheLastModifiedFactor` is set to 0.1, meaning that the expiry date for such documents equals one-tenth of the amount of time since the document was last modified.

`CacheDefaultExpire` is the expiry time in hours for a document that was received using a protocol that does not support expiry times. The default is set to one hour.

Any document that is retrieved from a host or domain that matches one set in `NoCache` will not be cached. If you know of hosts or domains from which you do not want to cache documents, uncomment `NoCache` and set their domains or hostnames here.

14.5.69. NameVirtualHost

You will need to use the `NameVirtualHost` directive for the IP address and port number, if necessary, of any name-based virtual hosts you are setting up. The name-based virtual hosts configuration is used when you want to set up different virtual hosts for different domains, but you do not have or do not want to use different IP addresses for all of the different domain names for which your Web server serves documents.

**Note**

Any name-based virtual hosts you set up will only work with non-secure HTTP connections as you cannot use name-based virtual hosts with a secure server. If you need to use virtual hosts with a secure server, you will need to use IP address-based virtual hosts.

If you are using name-based virtual hosts, uncomment the `NameVirtualHost` configuration directive and add the correct IP address for your server after `NameVirtualHost`. Then add more information about the different domains using the `VirtualHost` tags which surround the `ServerName` for each virtual host, plus any other configuration directives which are only applicable to that virtual host.

14.5.70. VirtualHost

`<VirtualHost>` and `</VirtualHost>` tags surround any configuration directives which are intended to apply to a virtual host. Most configuration directives can be used within virtual host tags, and then they only apply to that particular virtual host.

A set of commented out `VirtualHost` tags surround some example configuration directives and placeholders for the information you would need to fill in to set up a virtual host. Please see Section 14.8, for more information about virtual hosts.

**Note**

All SSL virtual hosts contexts have been moved into the file `/etc/httpd/conf.d/ssl.conf`.

14.5.71. SetEnvIf

The Apache configuration directive `SetEnvIf` can be used to set environment variables based on headers in the request. In the supplied `httpd.conf` file, it is used to disable HTTP keepalive and to allow SSL to close the connection without a close notify alert from the client browser. This setting is necessary for certain browsers that do not reliably shut down the SSL connection.

14.5.72. SSL Configuration Directives

The SSL directives in `/etc/httpd/conf.d/ssl.conf` file can be configured to enable secure Web communications using SSL and TLS.

For more information on SSL directives, please point your browser to http://localhost/manual/mod/mod_ssl.html or the Apache group `mod_ssl` documentation at http://httpd.apache.org/docs-2.0/mod/mod_ssl.html.

For information about setting up an Apache HTTP Secure Server see the chapter titled *Apache HTTP Secure Server Configuration* in the *Official Red Hat Linux Customization Guide*.

**Note**

Do not modify your SSL directives unless you are absolutely sure about what you are doing. In most cases, the SSL directives are configured appropriately as installed.

14.6. Default Modules

The Apache HTTP Server is distributed with a number of modules. By default the following modules are installed and enabled with the `httpd` package on Red Hat Linux:

```
mod_access
mod_auth
mod_auth_anon
mod_auth_dbm
mod_auth_digest
mod_include
mod_log_config
mod_env
mod_mime_magic
mod_cern_meta
mod_expires
mod_headers
mod_usertrack
mod_unique_id
mod_setenvif
mod_mime
mod_dav
mod_status
mod_autoindex
mod_asis
mod_info
mod_cgi
mod_dav_fs
mod_vhost_alias
mod_negotiation
mod_dir
mod_imap
mod_actions
mod_speling
mod_userdir
mod_alias
mod_rewrite
```

Additionally, the following modules are available by installing additional packages:

```
mod_auth_mysql
mod_auth_pgsqldb
mod_perl
mod_python
mod_ssl
php
squirrelmail
```

14.7. Adding Modules to Your Server

Since the Apache HTTP Server 2.0 supports DSOs, you can easily load Apache modules or compile in your own modules. DSO support also means modules are dynamically loaded at runtime only as necessary, conserving memory resources on the server.

The Apache Group provides complete DSO Documentation at <http://httpd.apache.org/docs-2.0/dso.html>. After installation of the `http-manual` package, you can also check <http://localhost/manual/mod/> for documentation on Apache modules.

For the Apache HTTP Server to use a dynamically shared module, that module must have a `LoadModule` line in `httpd.conf`.

A sample `LoadModule` line looks like this:

```
LoadModule access_module modules/mod_access.so
```

If you add or delete modules from `httpd.conf`, you must reload or restart Apache, as covered in Section 14.4.

If you have your own module, you can add it to the `httpd.conf` file so that it is compiled in and loaded as a DSO. For this you need have the `httpd-devel` package installed because it contains the include files, the header files, and the *APache eXtension* (`apxs`) application. The `apxs` command uses the include files and the header files to compile Apaches modules.

If you have written your own module or are using a third party module, you should be able to use `apxs` to compile your module sources outside the Apache source tree, without needing to tweak any compiler or linker flags. If you need more information on `apxs`, please see the Apache documentation at <http://httpd.apache.org/docs-2.0/dso.html> and the `apxs`, man page.

Once you have compiled the module, put your module in the `/usr/lib/httpd/` directory. Then add a `LoadModule` line to `httpd.conf`. After the `LoadModule` list in `httpd.conf`, add a line for the shared object file for your module like the following:

```
LoadModule <foo_module> modules/<mod_foo.so>
```

Note that you will need to change the name of `<foo_module>` and `<mod_foo.so>` as appropriate.

Once you have completed these steps, stop and start your Web server as outlined in Section 14.4. If you have done everything correctly and your module is correctly coded, the Web server should find your module and load it.

14.8. Using Virtual Hosts

You can use the Apache HTTP Server's virtual hosts capability to run different servers for different IP addresses, different host names, or different ports on the same server. If you are interested in using virtual hosts, complete information is provided in the Apache documentation on your machine or on the Web at <http://httpd.apache.org/docs-2.0/vhosts/>.

Note

You cannot use name-based virtual hosts with your Red Hat Linux Advanced Server, because the SSL handshake occurs before the HTTP request which identifies the appropriate name-based virtual host. If you want to use name-based virtual hosts, they will only work with your non-secure Web server.

Virtual hosts are configured within the `httpd.conf` file, as described in Section 14.5. Please review that section before you start to change the virtual hosts configuration on your machine.

14.8.1. The Secure Web Server Virtual Host

The default configuration of your Web server runs a non-secure and a secure server. Both servers use the same IP address and host name, but they listen on different ports, and the secure server is a virtual host configured. This configuration enables you to serve both secure and non-secure documents in a manner. Setting up the secure HTTP transmission is very resource intensive, so generally you will be able to serve far fewer pages per second with a secure server. You need to consider this when you decide what information to include on the secure server and the non-secure server.

The configuration directives for your secure server are contained within virtual host tags in the `/etc/httpd/conf.d/ssl.conf` file. If you need to change anything about the configuration of your secure server, you will need to change the configuration directives inside the virtual host tags.

By default, both the secure and the non-secure Web servers share the same `DocumentRoot`. To change the `DocumentRoot` so that it is no longer shared by both the secure server and the non-secure server, change one of the `DocumentRoot` directives. The `DocumentRoot` either inside or outside of the virtual host tags in `httpd.conf` defines the `DocumentRoot` for the non-secure Web server. The `DocumentRoot` within the virtual host tags in `conf.d/ssl.conf` define the document root for the secure server.

The secure the Apache HTTP Server server listens on port 443, while your non-secure Web server listens on port 80. To stop the non-secure Web server from accepting connections find the line which reads:

Then comment out any line in `httpd.conf` which reads `Listen 80`.

14.8.2. Setting Up Virtual Hosts

To create a virtual host, you will need to alter the virtual host lines, provided as an example in `httpd.conf` or create your own virtual host section.

The virtual host example lines read as follows:

```
#<VirtualHost *>
#   ServerAdmin webmaster@dummy-host.example.com
#   DocumentRoot /www/docs/dummy-host.example.com
#   ServerName dummy-host.example.com
#   ErrorLog logs/dummy-host.example.com-error_log
#   CustomLog logs/dummy-host.example.com-access_log common
#</VirtualHost>
```

Uncomment all of the lines, and add the correct information for the virtual host.

In the first line, change `*` to your server's IP address. Change the `ServerName` to a *valid* DNS name to use for the virtual host.

You will also need to uncomment one of the `NameVirtualHost` lines below:

```
NameVirtualHost *
```

Next change the IP address to the IP address, and port if necessary, for the virtual host. When finished it will look similar to the following example:

```
NameVirtualHost 192.168.1.1:80
```

If you set up a virtual host and want it to listen on a non-default port, you will need to set up a virtual host for that port and add a `Listen` directive for corresponding to that port.

Then add the port number to the first line of the virtual host configuration as in the following example:

```
<VirtualHost ip_address_of_your_server:12331>
```

This line would create a virtual host that listens on port 12331.

You must restart `httpd` to start a new virtual host. See Section 14.4 for instructions on how to start and stop `httpd`.

Comprehensive information about creating and configuring both name-based and IP address-based virtual hosts is provided on the Web at <http://httpd.apache.org/docs-2.0/vhosts/>.

14.9. Additional Resources

To learn more about the Apache HTTP Server, refer to the following resources.

14.9.1. Useful Websites

- <http://httpd.apache.org> — The official website for the Apache Web server with documentation on all the directives and default modules.
- <http://www.modssl.org> — The official website for mod_ssl.
- <http://www.apacheweek.com> — A comprehensive online weekly about all things Apache.

14.9.2. Related Books

- *Apache Desktop Reference* by Ralf S. Engelschall; Addison Wesley
Written by ASF member and mod_ssl author Ralf Engelschall, the *Apache Desktop Reference* provides a concise but comprehensive reference guide to using Apache at compilation, configuration, and run time. This book is available online at <http://www.apacheref.com/>.
- *Professional Apache* by Peter Wainwright; Wrox Press Ltd
Professional Apache is from Wrox Press Ltd's "Programmer to Programmer" series and is aimed at both experienced and novice Web server administrators.
- *Administering Apache* by Mark Allan Arnold; Osborne Media Group
This book is targeted at Internet Service Providers who aim to provide more secure services.
- *Apache Server Unleashed* by Richard Bowen, et al; SAMS BOOKS
An encyclopedic source for Apache.
- *Apache Pocket Reference* by Andrew Ford, Gigi Estabrook; O'Reilly
This is the latest addition to the O'Reilly Pocket Reference series.

Email is one of the most widely used services on the Internet. Red Hat Linux offers many ways to serve and access email, whether you are a desktop user or a system administrator.

This chapter looks at popular email protocols that are in use today and some of the programs designed to deal with email.

15.1. Protocols

Email, like other network services, uses a variety of protocols. These protocols allow different machines, often running different operating systems and using different email programs, to communicate with one another via email.

The following protocols are the most commonly used to transfer email from system to system.

15.1.1. IMAP

The *Internet Message Access Protocol (IMAP)* is a method used by email client applications to access remotely stored messages. When using IMAP email messages remain on the remote mail server where users can read or delete them and create, rename, or delete mailboxes to store the email.

In addition, IMAP is fully compatible with important Internet messaging standards, such as the Multipurpose Internet Mail Extensions (MIME), to allow for receiving attachments. Many email clients that use IMAP can also be configured to cache a copy of the messages locally, so that you can browse previously read messages when you are not directly connected to the IMAP server.

IMAP is primarily used by those who access their email using multiple machines. Also, users that connect to the Internet or a private network via a low-bandwidth connection often use IMAP because only the email header information is pulled off at first. This allows them to defer the downloading of messages containing large attachments until a time when their limited bandwidth is not in use. In the same way, email that the user does not want can be deleted without viewing the message body, saving the need to even download it through their network connection.

The *Request for Comment (RFC)* documents that cover IMAP contain the assorted details and specifics about how the protocol is designed to work. RFC-1730 first defined the way IMAP is used in version 4, but RFC-2060 discusses the IMAP implementation used with many IMAP servers, called version IMAP4rev1.

The `imap` package in Red Hat Linux allows users to connect to your system and receive their email using IMAP. Secure IMAP connections are supported through Secure Socket Layer (SSL) technology built into the `/usr/sbin/imapd` daemon, allowing it to use the `/usr/share/ssl/certs/imapd.pem` certificate file. The `stunnel` program is not required to provide SSL-encryption for IMAP connections, though it can be used. See Section 15.6.2 for more information concerning these two encryption options.

Other free, as well as commercial, IMAP clients and servers are available, many of which extend the IMAP protocol and provide additional functionality. A comprehensive list can be found at <http://www.imap.org/products/longlist.htm>.

15.1.2. POP

The *Post Office Protocol (POP)* allows email clients to download email from remote servers and save those messages on their local machine. Most POP email clients are automatically configured to delete

the message on the email server after it has been successfully transferred to the client's system, though this can usually be changed.

To connect to a POP server, the email client opens a TCP connection to port 110 on the server. At the time the connection is made, the POP server sends the POP client a greeting, after which the two machines send each other commands and responses specified in the protocol. As part of this communication, the POP client is asked to authenticate itself in what is called the *Authentication State*, where the user's username and password are sent to the POP server. If authentication is successful, then the POP client moves on to the *Transaction State*, where commands like `LIST`, `RETR`, and `DELE` can be used to list, download, and delete the messages from the server. Messages set to be deleted are not actually removed from the server until the POP client sends the `QUIT` command to end the session. At this point, the POP server enters the *Update State*, where it deletes the flagged messages and cleans up any resources remaining from the session.

POP is a much simpler protocol than IMAP, since fewer commands are sent between the client and the server.

POP works best for users who only have one system to read email with since they download their messages to that machine. POP also works well if you do not have a constant connection to the Internet or the network containing your mail server.

Several RFCs cover the POP protocol, but RFC-1939 defines the basic outline of POP3, the current version.

Occasionally, you may run into lesser-used POP protocol variants:

- *APOP* — POP3 with MDS authentication, where an encoded hash of your password is sent from the email client to the server rather than sending the password in plain text.
- *KPOP* — POP3 with Kerberos authentication. See Chapter 10 for more information concerning Kerberos authentication.
- *RPOP* — POP3 with RPOP authentication, which uses an ID issued per user, similar to a password, to authenticate POP requests. However, this ID is not encrypted, so RPOP is no more secure than standard POP.

Many POP servers, clients, and assorted other applications are available with Red Hat Linux. If you prefer a graphical email client, either **Mozilla Mail** or **Ximian Evolution** is a good choice. In addition, other email utilities, such as Fetchmail, can retrieve email via POP. If you are using your Red Hat Linux system as a mail server, the `imap` package installs POP2 (`ipop2`) and POP3 (`ipop3`) daemons in the `/usr/sbin/` directory.

15.1.3. SMTP

While the IMAP and POP protocols involve allowing a user to be able to receive their email, the *Simple Mail Transfer Protocol (SMTP)* is used to send email. Outgoing email uses SMTP to move from the client's machine to the server, on its way toward its final destination. Email servers attempting to move a message between one another also use SMTP to communicate.

SMTP uses port 25 on the server for communication. A basic SMTP exchange begins with the connecting system issuing a `MAIL From: <email-address>` command to initiate exchange. The receiving system responds with a `250` message to acknowledge receipt of the first command. Then, the connecting system hands the email addresses to receive the message to the receiving system, followed by a `DATA` message. This tells the receiving system that the next part of the communication will be the actual body of the email message. When the connecting system is finished with the email message, it places a single dot (`.`) on a line. At that point, the message is considered sent.

SMTP also handles cases where email needs to be forwarded between systems, when the receiving system knows where to send the message. The protocol can verify that certain users are served by a

particular mail server using the `VERFY` command or expand a mailing list using the `EXPN` command. Email can also be relayed between two SMTP servers, if both systems permit such activity.

Unlike IMAP and POP, the SMTP protocol does not require authentication. This means that SMTP servers can allow anyone on the Internet to use your system to send or relay mail to large lists of recipients. It is this characteristic of SMTP that makes spam possible. Modern SMTP applications attempt to minimize this behavior by restricting relaying and allowing only known hosts to send email.

RFC-821 outlines the basic behavior of SMTP, but several SMTP extensions, made possible by RFC-1869, have added additional functionality to SMTP over the years by making new commands available. By initiating a conversation with an SMTP server with an `EHLO` command rather than `HELO`, the connecting server can identify itself as one that supports SMTP extensions. The receiving server answers with a `250` line containing the various SMTP extensions it supports. Then, the connecting server can use the supported extensions as it wishes to accomplish the goals of the communication.

One extension adds SMTP Authentication through the `AUTH` command as outlined in RFC-2554. Another widely used SMTP extension, detailed in RFC-2034, discusses the use of dot-separated, standardized error codes for use between SMTP applications. Reading the various RFCs that involve SMTP provides a background to the way email moves around the Internet. In addition, you can connect to an SMTP server via telnet by specifying port 25, such as `telnet localhost 25`. Executing a few commands and sending a mail manually is a good way to understand how SMTP communications work.

Red Hat Linux 8.0 uses Sendmail (`/usr/sbin/sendmail`) as its SMTP program by default. However, an easier to use application called Postfix (`/usr/sbin/postfix`) is also available for use. Section 15.2.2 for more on this topic.

15.2. Email Program Classifications

In general, all email applications fall into at least one of three classifications. Each of these classifications plays a specific role in the process of moving and managing email messages. While most users are only aware of the specific email program they use to receive and send messages, each of these types is important for making sure email arrives at the correct destination.

15.2.1. Mail User Agent

A *Mail User Agent (MUA)* is a program that, at the very least, allows a user to read and compose email messages. An MUA is often referred to as an *email client*. Of course, many MUAs help users do more than that, including retrieving messages via the POP or IMAP protocols, setting up mailboxes to store messages, or helping present new messages to a Mail Transfer Agent that will deliver them to their final destination.

MUA programs may be graphical, such as **Mozilla Mail**, or have a very simple, text-based interface, such as `mutt`.

15.2.2. Mail Transfer Agent

A *Mail Transfer Agent (MTA)* transfers email messages between machines using SMTP. A message may involve several MTAs as it moves to its intended destination. Most users are totally unaware of the presence of MTAs, even though every email message is sent through at least one MTA.

While the delivery of messages between machines may seem rather straightforward, the entire process of deciding if a particular MTA can or should accept a message for delivery is quite complicated. In addition, due to problems from spam, use of a particular MTA is usually restricted by the MTA's own configuration or network access to the system running it.

Many of the larger and more complex MUAs can also be used to send email. However, this action should not be confused with the actions of a true MTA. In order for users not running their own MTA to move outbound messages off of their machine and onto a remote machine for delivery, they must use a capacity in the MUA that transfers the message to an MTA they are authorized to use. However, the MUA does not directly deliver the message to the intended recipient's email server — that role is reserved for the MTA.

Red Hat Linux uses Sendmail as its default MTA, though others may be used in its place.

**Tip**

For information about how to switch the default MTA from Sendmail to Postfix, see the chapter called *Mail Transport Agent (MTA) Configuration* in the *Official Red Hat Linux Customization Guide*.

15.2.3. Mail Delivery Agent

A *Mail Delivery Agent (MDA)* is used by the MTA to deliver email to a particular user's mailbox. In many cases, an MDA is actually a *Local Delivery Agent (LDA)*, such as `/bin/mail` or `procmail`. However, Sendmail can also play the role of an MDA, such as when it accepts a message for a local user and appends it to their email spool file. Any program that actually handles a message for delivery to the point where it can be read by an MUA can be considered an MDA. Note that MDAs do not transport messages between systems or interface with the end user.

Many users do not directly use MDAs, because only MTAs and MUAs are necessary to send and receive email. However, some MDAs may be used to sort messages before they are read by a user, which is a big help if you receive a lot of email.

15.3. Sendmail

Red Hat Linux uses Sendmail as its default MTA, whether they are intended for users on the same system or for remote destinations. Other MTAs do exist, but many system administrators elect to use Sendmail as their MTA due to its power, scalability, and compliance to important Internet standards, such as SMTP.

Sendmail's core duty, like other MTAs, is to safely move email between hosts, usually using the SMTP protocol. However, Sendmail is highly configurable, allowing you to control almost every aspect of how email is handled, including the protocol used.

15.3.1. History

Sendmail's roots can be traced to the birth of email, occurring in the decade before the birth of ARPANET, the precursor to the Internet. In those days, every user's mailbox was a file that only they had rights to read, and mail applications simply added text to that file. Every user had to wade through their mail file to find any old mail, and reading new mail was a equally difficult. The first actual transfer of a mail message file from one host to another did not take place until 1972, when email began to be moved by FTP over the NCP network protocol. This easier method of communication quickly became popular, even to the point where it made up most of ARPANET's traffic in less than a year.

However, a lack of standardization between competing protocols made email much harder to send from some systems. This continued until the ARPANET standardized on TCP/IP in 1982. Soon after, a new protocol, SMTP, materialized for transporting email messages. These developments, combined with HOSTS files being replaced with DNS, allowed full-featured MTAs to materialize. Sendmail,

which grew out of an earlier email delivery system called Delivermail, quickly became the standard as the email began to expand and become widely used.

15.3.2. Purpose and Limitations

It is important to be aware of what Sendmail is and what it can do for you as opposed to what it is not. In these days of monolithic applications that fulfill multiple roles, you might initially think that Sendmail is the only application you need to run an email server within your organization. Technically, this is true, as Sendmail can spool mail to your users' directories and accepts new email via the command line. But, most users actually require much more than simple email delivery. They usually want to interact with their email using an MUA that uses POP or IMAP to download their messages to their local machine. Or, they may prefer a Web interface to gain access to their mailbox. These other applications can work in conjunction with Sendmail and SMTP, but they actually exist for different reasons and can operate separately from one another.

It is beyond the scope of this section to go into all that Sendmail should or could be configured to do. With literally hundreds of different options and rule sets, entire volumes are dedicated to helping explain everything that can be done and how to fix things that go wrong. You should consult the many excellent resources on Sendmail in order to shape it to fit your exact specifications.

However, you should understand what files are installed with Sendmail by default on your system and know how to make basic configuration changes. You should also be aware of how to stop unwanted email (spam) and how to extend Sendmail with the *Lightweight Directory Access Protocol (LDAP)*.

15.3.3. The Default Sendmail Installation

While you can download the source code for Sendmail and build your own copy, many users prefer to use the version of Sendmail installed by default with their Red Hat Linux system. You can also use the Red Hat Linux CD-ROMs to reinstall the `sendmail` RPM at a later point. Be aware that you must alter the default configuration file for Sendmail to use it as a mail server for more the localhost. See Section 15.3.4 for details.

After installation, the `sendmail` executable is placed in the `/usr/sbin/` directory.

Sendmail's lengthy and detailed configuration file, `sendmail.cf`, is installed in the `/etc/mail/` directory. You should avoid editing the `sendmail.cf` file directly. Instead, to make configuration changes to Sendmail, edit the `/etc/mail/sendmail.mc` file, back up the original `/etc/mail/sendmail.cf`, and then use the included `m4` macro processor to create a new `/etc/mail/sendmail.cf`. More information on configuring Sendmail can be found in Section 15.3.4.

Various Sendmail configuration files are installed in the `/etc/mail/` directory including:

- `access` — Specifies which systems can use Sendmail for relaying email.
- `domaintable` — Allows you to provide domain name mapping.
- `local-host-names` — The place where you include all aliases for your machine.
- `mailertable` — Specifies instructions that override routing for particular domains.
- `virtusertable` — Permits you to do a domain-specific form of aliasing, allowing multiple virtual domains to be hosted on one machine.

Several of the configuration files in `/etc/mail/`, such as `access`, `domaintable`, `mailertable` and `virtusertable`, must actually store their information in database files before Sendmail can use any configuration changes. To include any changes you make to these configurations in their database files, you must run the `makemap` hash `/etc/mail/<name> < /etc/mail/<name>` command, where `<name>` is the name of the configuration file to convert.

For example, if you want all email addressed to any `domain.com` account to be delivered to `<bob@otherdomain.com>`, you need to add a line similar to the one below to the `virtusertable` file:

```
@domain.com      bob@otherdomain.com
```

Then, to add this new information to the `virtusertable.db` file, execute `makemap hash /etc/mail/virtusertable < /etc/mail/virtusertable` as root. This will create a new `virtusertable.db` containing the new configuration.

15.3.4. Common Sendmail Configuration Changes

Although a default `sendmail.cf` file is installed in `/etc/mail/` during the Red Hat Linux installation process, you will need to alter it to use some of the program's more advanced features.

When altering the Sendmail configuration file, it is best generate a entirely new `/etc/mail/sendmail.cf` file instead of editing an existing one.

Caution

Before changing the `sendmail.cf` file, it is a good idea to backup the default version.

To add the desired functionality Sendmail edit the `/etc/mail/sendmail.mc` file. When you are finished, use the `m4` macro processor to generate a new `sendmail.cf` by executing the `m4 /etc/mail/sendmail.mc > /etc/mail/sendmail.cf` command. After creating a new `/etc/mail/sendmail.cf`, you must restart Sendmail to make it take effect. The easiest way to do this is to type the `/sbin/service sendmail restart` command as root.

By default, the `m4` macro processor is installed with Sendmail and is part of the `sendmail-cf` package.

Important

The default `sendmail.cf` does not allow sendmail to accept network connections from any host other than the local computer. If you want to configure sendmail as a server for other clients, please edit `/etc/mail/sendmail.mc` and change `DAEMON_OPTIONS` to also listen on network devices or comment out this option all together. Then regenerate `/etc/mail/sendmail.cf` by running:

```
m4 /etc/mail/sendmail.mc > /etc/mail/sendmail.cf
```

This configuration should work for most SMTP-only sites. It will *not* work for UUCP (UNIX to UNIX Copy) sites; you will need to generate a new `sendmail.cf` if you must use UUCP mail transfers.

You should consult the `/usr/share/sendmail-cf/README` file before you edit any of the files in the directories under the `/usr/share/sendmail-cf` directory, as they can affect how future `/etc/mail/sendmail.cf` files are configured.

15.3.4.1. Masquerading

One common Sendmail configuration is to have a single machine act as a mail gateway for all the machines on the network. For instance, a company may want to have a machine called `mail.bigcorp.com` that handles all their email and assigns a consistant return address to all out going mail.

In this situation, the sendmail server needs to masquerade the machine names on the company network so that their return address is `user@bigcorp.com` instead of `user@devel.bigcorp.com`.

To do this, add the following lines to `/etc/mail/sendmail.mc`.

```
FEATURE(always_add_domain)dnl
FEATURE('masquerade_entire_domain')
FEATURE('masquerade_envelope')
FEATURE('allmasquerade')
MASQUERADE_AS('bigcorp.com.')
MASQUERADE_DOMAIN('bigcorp.com.')
MASQUERADE_AS(bigcorp.com)
```

After generating a new `sendmail.cf` using `m4`, this configuration will make all mail from inside the network appear as if it were sent from `bigcorp.com`.

15.3.5. Stopping Spam with Sendmail

Email *spam* can be defined as unnecessary and unwanted email received by a user who never requested the communication. It is a disruptive, costly, and widespread abuse of Internet communication standards.

Sendmail has made it relatively easy to block new spamming techniques being employed to send junk email using your system. It even blocks many of the more usual spamming methods by default. You would need to consciously activate them by changing your `/etc/mail/sendmail.mc` file in a particular way to make your system susceptible.

For example, forwarding of SMTP messages, also referred to as *SMTP relaying*, has been disabled by default since Sendmail version 8.9. Before this change occurred, Sendmail would direct your mail host (`x.org`) to accept messages from one party (`y.com`) and send them to a different party (`z.net`). Now, however, you have to specifically tell Sendmail to permit a domain to relay mail through your domain. Simply edit the `/etc/mail/relay-domains` file and restart Sendmail by typing the `service sendmail restart` command as root to activate the changes.

However, many times, your users may be bombarded with spam from other servers throughout the Internet that are beyond your control. In these instances, you can use Sendmail's access control features available through the `/etc/mail/access` file. As root, add the domains that you would like to block or specifically allow access, such as in this example:

```
badspammer.com      550 Go away and do not spam us anymore
tux.badspammer.com  OK
10.0                 RELAY
```

Because `/etc/mail/access.db` is a database, you need to use `makemap` to activate your changes by recreating the database map. This is easily done by running the `makemap hash /etc/mail/access < /etc/mail/access` command as root.

This example shows that any email sent from `badspammer.com` would be blocked with a 550 RFC-821 compliant error code and message back to the spammer, except for email sent from the `tux.badspammer.com` sub-domain, which would be accepted. The last line shows that any email sent from the `10.0.*.*` network can be relayed through your mail server.

As you might expect, this example only scratches the surface of what Sendmail can do in terms of allowing or blocking access. See the `/usr/share/doc/sendmail/README.cf` for more detailed information and examples.

15.3.6. Using Sendmail with LDAP

Using the *Lightweight Directory Access Protocol (LDAP)* is a very quick and powerful way to find specific information about a particular user from a much larger group. For example, you could use an LDAP server to look up a particular email address from a common corporate directory by a user's last name. In this kind of implementation, LDAP is largely separate from Sendmail, with LDAP storing the hierarchical user information and Sendmail only being given the result of LDAP queries in pre-addressed email messages.

However, Sendmail supports a much greater integration with LDAP, where it uses LDAP to replace separately maintained files, such as `aliases` and `virtusertables`, on different mail servers that work together to support a medium- to enterprise-level organization. In short, you can use LDAP to abstract the mail routing level from Sendmail and its separate configuration files to a powerful LDAP cluster that is being leveraged by many different applications.

The current version of Sendmail contains support for LDAP. To extend your Sendmail server using LDAP, first get an LDAP server, such as **OpenLDAP**, running and properly configured. Then, you need to edit your `/etc/mail/sendmail.mc` to include the following:

```
LDAPROUTE_DOMAIN('yourdomain.com') dnl
FEATURE('ldap_routing') dnl
```

Note

This is only for a very basic configuration of Sendmail with LDAP. Your configuration should differ greatly from this depending on your implementation of LDAP, especially if you wish to configure several Sendmail machines to use a common LDAP server.

Consult `/usr/share/doc/sendmail/README.cf` for detailed LDAP routing configuration instructions and examples.

Next, recreate your `/etc/mail/sendmail.cf` file by running `m4` and restarting Sendmail. See Section 15.3.4 for instructions on doing this.

For more information on LDAP, see Chapter 18.

15.4. Fetchmail

Fetchmail is a program that can retrieve email from remote servers for on-demand TCP/IP connections. Many users appreciate the ability to separate the process of downloading their messages located on a remote server from the process of reading and organizing their email in an MUA. Designed with the needs of dial-up users in mind, Fetchmail will connect and quickly download all of your email messages to your mail spool file using any number of protocols, including the POP3 and IMAP. It can even forward your email messages to an SMTP server, if necessary.

Before attempting to use Fetchmail, be sure that it is installed on your system. If it is not, you can install it using the `fetchmail` RPM on the Red Hat Linux CD-ROMs.

Fetchmail is configured for each user through the use of a `.fetchmailrc` file in the user's home directory. A program bundled with Fetchmail, called `fetchmailconf`, is very helpful for configuring a basic `.fetchmailrc` file that you can customize at will.

Using preferences in the `.fetchmailrc` file, Fetchmail will check for email on a remote server and pull it off, attempting to deliver it to port 25 on the local machine, using the local MTA to place the email in the correct user's spool file. If Procmail is available, it can then be used to filter the email and place it in a mailbox so that it can be read by an MUA.

15.4.1. Fetchmail Configuration Options

Although it is possible to pass all options on the command line necessary to check for email on a remote server when executing Fetchmail, using a `.fetchmailrc` file is much easier. All of your configuration options go in the `.fetchmailrc` file, but you can override them at the time Fetchmail is run by specifying that option on the command line.

A user's `.fetchmailrc` file is divided into three particular types of configuration options:

- *global options* — Gives Fetchmail instructions that control the operation of the program or provide settings for every connection that checks for email.
- *server options* — Specifies necessary information about the server being polled, such as the host-name, as well as preferences you would like to see enforced with a particular email server, such as the port to check or number of seconds to wait before timing out. These options affect every user option used with that server.
- *user options* — Contains information, such as username and password, necessary to authenticate and check for email using a particular email server.

Global options go at the top of the `.fetchmailrc` file, followed by one or more server options, each of which designate a different email server that Fetchmail should check. User options follow server options for each user account you would like to check on that email server. Like server options, multiple user options may be specified for use with a particular server, such as when you would like to check multiple email accounts on the same server.

Server options are called into service in the `.fetchmailrc` file by the use of a special option verb, `poll` or `skip`, that precedes any of the server information. The `poll` action tells Fetchmail to use this server option when it is run, which actually checks it for email using the various user options. Any server options after a `skip` action, however, are not checked unless you specify this server's hostname when Fetchmail is invoked. The `skip` option allows you to set up test configurations in `.fetchmailrc` and only check using that server when specifically desired, without affecting any currently working configurations.

A sample `.fetchmailrc` file looks like this:

```
set postmaster "user1"
set bouncemail

poll pop.domain.com proto pop3
    user 'user1' there with password 'secret' is user1 here

poll mail.domain2.com
    user 'user5' there with password 'secret2' is user1 here
    user 'user7' there with password 'secret3' is user1 here
```

In this example, the global are options set so the user is sent email as a last resort (`postmaster` option) and all email errors are sent to the postmaster instead of the sender (`bouncemail` option). The `set` action tells Fetchmail that this line contains a global option. Then, two email servers are specified, one set to check using POP3, and the other for trying various protocols to find one that works. Two users are checked using the second server option, but all email found for any users is sent to user1's mail spool. This allows multiple mailboxes to be checked on multiple servers, while appearing in a single MUA inbox. Each user's specific information begins with the `user` action.

Note

You do not have to place your password in the `.fetchmailrc` file. You can omit the `with password '<password>'` section. Fetchmail will then ask for your password when it is started with the `fetchmail` command.

While you can set up your `.fetchmailrc` file manually, it is much easier to let the included `fetchmailconf` program do it for you. However, when testing new configurations, it is usually easier to edit the `.fetchmailrc` file directly.

As expected with a program that services such a mature network service as email and uses so many protocols, Fetchmail contains many different global, server, and local options. Many of these options are rarely used or only apply to very specific situations. The `fetchmail` man page explains each of these options in detail, but the most common ones are listed here.

15.4.1.1. Global Options

Each global option should be placed on a single line after a `set` action.

- `daemon <seconds>` — Tells Fetchmail to automatically use daemon-mode, where it will stay in the background and poll for mail at the interval specified.
- `postmaster` — Gives Fetchmail a local user to send mail to in case of delivery problems.
- `syslog` — Tells Fetchmail to start logging error and status messages in the system's log file. By default, this is `/var/log/maillog`.

15.4.1.2. Server Options

Place server options on their own line in `.fetchmailrc` after a `poll` or `skip` action.

- `auth <auth-type>` — Specifies the type of authentication to be used. By default, `password` authentication is used, but some protocols support other types of authentication, including `kerberos_v5`, `kerberos_v4`, and `ssh`. If the `any` authentication type is used, Fetchmail will first try methods that do not require a password, then methods that mask your password, and finally attempt to send your password in the clear to authenticate to the server.
- `interval <number>` — Tells Fetchmail to only poll this server every `<number>` of times that it checks for email on all configured servers. This option might be used with email servers where you rarely receive messages.
- `port <port-number>` — Overrides the default port number for a specified protocol.
- `proto <protocol>` — Tells Fetchmail to use a specific protocol, such as `pop3` or `imap`, to check for messages on this server.
- `timeout <seconds>` — Configures Fetchmail to give up after a certain interval of server inactivity. If this value is not set, a default of 300 seconds is assumed.

15.4.1.3. User Options

User options may be placed on their own lines beneath a server option or on the same line as the server option. In either case, the user options follow the `user` option (defined below).

- `fetchall` — Orders Fetchmail to download all messages in the queue, including messages that have already been viewed. By default, Fetchmail only pulls down new messages.
- `fetchlimit <number>` — Only allows a certain number of messages to be retrieved before stopping.
- `flush` — Tells Fetchmail to delete all previously viewed messages in the queue before retrieving new messages.

- `limit <max-number-bytes>` — Allows you to specify that only messages below a particular size may be retrieved. This option is useful with slow network links, when a large message will take too long to download.
- `password '<password>'` — Specifies the password to be used for this user.
- `preconnect "<command>"` — Tells Fetchmail to execute the specified command before retrieving messages for this user.
- `postconnect "<command>"` — Tells Fetchmail to execute the specified command after retrieving messages for this user.
- `ssl` — Allows Fetchmail to collect the message via an encrypted SSL connection, if the server supports this.
- `user "<username>"` — Sets the username used by Fetchmail to retrieve messages. This option should be listed before any other user options.

15.4.2. Fetchmail Command Options

Most of the Fetchmail options that may be used on the command line, when executing the `fetchmail` command, mirror the `.fetchmailrc` configuration options. This is done so that Fetchmail may be used with or without a configuration file. Most users will not use these options on the command line, as it is easier to leave them in the `.fetchmailrc` file to be used whenever Fetchmail is run.

However, there are times when you may want to run the `fetchmail` command with other options for a particular purpose. As any options specified at the command line override configuration file options, you can also issue command options to temporarily override a `.fetchmailrc` setting that is causing an error.

15.4.2.1. Informational or Debugging Options

Certain options used after the `fetchmail` command can provide you with important information.

- `--configdump` — Displays every possible option based on information from `.fetchmailrc` and Fetchmail defaults. No email is retrieved for any users when using this option.
- `-s` — Executes Fetchmail in silent mode, preventing any messages, other than errors, from appearing after the `fetchmail` command.
- `-v` — Executes Fetchmail in verbose mode, displaying every communication between Fetchmail and the remote email servers.
- `-V` — Causes Fetchmail to display detailed version information, list its global options, and show settings to be used with each user, including the email protocol and authentication method. No email is retrieved for any users when using this option.

15.4.2.2. Special Options

These options are occasionally useful for overriding defaults often found in the `.fetchmailrc` file.

- `-a` — Tells Fetchmail to download all messages from the remote email server, whether new or previously viewed. By default, Fetchmail will only download new messages.
- `-k` — Causes Fetchmail to leave the messages on the remote email server after downloading them. This option overrides the default behavior of deleting messages after downloading them.
- `-l <max-number-bytes>` — Tells Fetchmail to not download any messages over a particular size and leave them on the remote email server.

- `--quit` — Quits the Fetchmail daemon process.

More commands and `.fetchmailrc` options can be found on the `fetchmail` man page.

15.5. Procmail

Procmail allows you to filter email as it is received from a remote email server, or placed in your spool file on a local or remote email server. It is powerful, gentle on system resources, and widely used. Procmail, commonly referred to as a *Local Delivery Agent (LDA)*, plays a small role in delivering email to be read by an MUA.

In order to use Procmail, it must first be installed. Type the `rpm -q procmail` command to see if the `procmail` package is installed. If, for some reason, Procmail is not on your system, install it from the Red Hat Linux installation CD-ROMs.

Procmail can be invoked in several different ways. As email is placed on your email spool file, Procmail can be configured to start up, filter the email to locations configured for use with your MUA, and quit. Or, your MUA could be configured to bring up Procmail any time a message is received so that messages are moved into their correct mailboxes. In many cases, the presence of a `.procmailrc` file in the user's home directory will invoke Procmail, if Sendmail is being used.

The actions Procmail takes with an email are dependent upon instructions from particular *recipes*, or rules, that messages are matched against by the program. If a message matches the recipe, then the email will be placed in a certain file, deleted, or otherwise processed.

When Procmail starts, it reads the email message and separates the body from the header information. Next, Procmail looks for the `/etc/procmailrc` file and `rc` files in the `/etc/procmailrcs` directory for default, system-wide, Procmail environmental variables and recipes. Then, Procmail looks for a `.procmailrc` file in the user's home directory to find rules specific to that user. Many users also create additional `rc` files of their own for Procmail that are referred to by their `.procmailrc` file but may be turned on or off quickly if a mail filtering problem develops.

By default, no system-wide `rc` files exist in the `/etc` directory, and no user `.procmailrc` files exist. To begin using Procmail, you will need to construct a `.procmailrc` file with particular environment variables and recipes explaining what you would like to do with certain messages.

In most configurations, the decision as to whether Procmail starts and attempts to filter your email is based the existence of a user's `.procmailrc` file. To disable Procmail, but save your work on the `.procmailrc` file, move it to a similar file's name using the `mv ~/.procmailrc ~/.procmail-rcSAVE` command. When you are ready to begin testing Procmail again, change the name of the file back to `.procmailrc`. Procmail will begin working again immediately.

15.5.1. Procmail Configuration

Procmail configuration files, most notably the user's `.procmailrc`, contain important environmental variables. These variables tell Procmail which messages to sort, what to do with the messages that do not match any recipes, and so on.

These environmental variables usually appear at the beginning of `.procmailrc` in the following format:

```
<env-variable>=<value>"
```

In this example, the `<env-variable>` is the name of the variable, and the `<value>` section defines the variable.

Many environment variables are not used by most Procmail users, and many of the more important environment variables are already defined a default value. Most of the time, you will be dealing with the following variables:

- **DEFAULT** — Sets the default mailbox where messages that do not match any recipes will be placed. The default **DEFAULT** value is the same as `$ORGMAIL`.
- **INCLUDERC** — Specifies additional `rc` files containing more recipes for messages to be checked against. This allows you to break up your Procmail recipe lists into individual files that fulfill different roles, such as blocking spam and managing email lists, that can then be turned off or on by using comment characters in the user's `.procmailrc` file.

For example, two lines in a user's `.procmailrc` file may look like this:

```
MAILDIR=$HOME/Msgs
INCLUDERC=$MAILDIR/lists.rc
INCLUDERC=$MAILDIR/spam.rc
```

If the user would like to turn off the Procmail filtering of their email lists but leave spam control in place, they could simply comment out the first **INCLUDERC** line with a `#` character.

- **LOCKSLEEP** — Sets the amount of time, in seconds, between attempts by Procmail to use a particular lockfile. The default is eight seconds.
- **LOCKTIMEOUT** — Sets the amount of time, in seconds, that must pass after a lockfile was last modified before Procmail will assume that the lockfile is simply old and can be deleted. The default is 1024 seconds.
- **LOGFILE** — The location and file to contain any Procmail informational or error messages.
- **MAILDIR** — Sets the current working directory for Procmail. If set, all other Procmail paths are relative to this directory.
- **ORGMAIL** — Specifies the original mailbox, or another place to put the messages if they cannot be placed in the default or recipe-required location. By default, a value of `/var/spool/mail/$LOGNAME` is used.
- **SUSPEND** — Sets the amount of time, in seconds, that Procmail will pause if a necessary resource, such as swap space, is not available.
- **SWITCHRC** — Allows a user to specify an external file containing additional Procmail recipes, much like the **INCLUDERC** option, except that recipe checking is actually stopped on the referring configuration file and only the recipes on the **SWITCHRC**-specified file are used.
- **VERBOSE** — Causes Procmail to log much more information. This option is useful for debugging.

Other important environmental variables are pulled from your shell, such as `LOGNAME`, which is your login name, `HOME`, which is the location of your home directory, and `SHELL`, which is your default shell.

A comprehensive explanation of all environments variables, as well as their default values, is available on the `procmailrc` man page.

15.5.2. Procmail Recipes

New users often find the construction of recipes the most difficult part of learning to use Procmail. To some extent, this is understandable, as recipes do their message matching using *regular expressions*, which is a particular format used to specify qualifications for a matching string. However, regular expressions are not very difficult to construct and even less difficult to understand when read. Additionally, the consistency of the way Procmail recipes are written, regardless of regular expressions, makes it easy to figure out what is going on.

A thorough explanation of regular expressions is beyond the scope of this chapter. The structure of Procmail recipes is more important, and useful sample Procmail recipes can be found at various places on the Internet, including <http://www.iki.fi/era/procmail/links.html>. The proper use and adaptation of the regular expressions found in these recipe examples depends upon an understanding of Procmail recipe structure. Introductory information specific to basic regular expression rules can be found on the `grep` man page.

A Procmail recipe takes the following form:

```
:0<flags>: <lockfile-name>
* <special-condition-character> <condition-1>
* <special-condition-character> <condition-2>
* <special-condition-character> <condition-N>

<special-action-character><action-to-perform>
```

The first two characters in a Procmail recipe are a colon and a zero. Various flags can optionally be placed after the zero to control what Procmail does when processing this recipe. A colon after the `<flags>` section specifies that a lockfile will be created for this message. If a lockfile is to be created, you specify its name in the `<lockfile-name>` space.

A recipe can contain several conditions to match against the message. If it has no conditions, every message will match the recipe. Regular expressions are placed in some conditions in order to facilitate a match with a message. If multiple conditions are used, they must all match in order for an action to be performed. Conditions are checked based on the flags set in the recipe's first line. Optional special characters placed after the `*` character can further control the condition.

The `<action-to-perform>` specifies what is to happen to a message if it matches one of the conditions. There can only be one action per recipe. In many cases, the name of a mailbox is used here to direct matching messages into that file, effectively sorting the email. Special action characters may also be used before the action is specified.

15.5.2.1. Delivering vs. Non-Delivering Recipes

The action used if the recipe matches a particular message determines whether recipe is considered delivering or non-delivering. A *delivering recipe* contains an action that writes the message to a file, sends the message to another program, or forwards the message to another email address. A *non-delivering recipe* covers any other actions, such as when a nesting block is used. A *nesting block* is an action contained in braces `{ }` that designates additional actions to perform on messages that match the recipe's conditions. Nesting blocks can be nested, providing greater control for identifying and performing actions on messages.

Delivering recipes that match messages causes Procmail to perform the action specified and stop comparing the message against any other recipes. Messages that match conditions in non-delivering recipes will continue to be compared against other recipes in the current and following `rc` files. In other words, non-delivering recipes cause the message to continue through the recipes after the specified action is taken on it.

15.5.2.2. Flags

Flags are very important in determining how or if a recipe's conditions are compared to a message. The following flags are commonly used:

- `A` — Specifies that this recipe will only be used if the last previous recipe without an `A` or `a` flag also matched this message.

To ensure that the action on this last previous matching recipe was successfully completed before allowing a match on the current recipe, use the `a` flag instead.

- `B` — Parse the body of the message and look for matching conditions.
- `b` — Use the body in any resulting action, such as writing the message to a file or forwarding it. This is the default behavior.
- `c` — Generate a carbon copy of the email. This is useful with delivering recipes, since the required action can be performed on the message and a copy of the message can continue being processed in the `rc` files.
- `D` — Makes the `egrep` comparison case-sensitive. By default, the comparison process is not case-sensitive.
- `E` — Similar to the `A` flag, except that the conditions in this recipe are only compared to the message if the immediately preceding recipe without an `E` flag did not match. This is comparable to an *else* action.

Use the `e` flag instead if you only want this recipe checked if the preceding recipe matched but the action failed.

- `f` — Uses the pipe as a filter.
- `H` — Parses the header of the message and looks for matching conditions. This occurs by default.
- `h` — Uses the header in a resulting action. This is the default behavior.
- `w` — Tells Procmail to wait for the specified filter or program to finish and report whether or not it was successful before considering the message filtered.

If you would like to ignore "Program failure" messages when deciding whether a filter or action succeeded, use the `W` option instead.

Additional flags can be found in the `procmailrc` man page.

15.5.2.3. Specifying a Local Lockfile

Lockfiles are very useful with Procmail to ensure that more than one process does not try to alter a certain message at the same time. You can specify a local lockfile by placing a colon (`:`) after any flags on a recipe's first line. This will create a local lockfile based on the destination filename plus whatever has been set in the `LOCKEXT` global environment variable.

Alternatively, you can specify the name of the local lockfile to be used with this recipe after the colon.

15.5.2.4. Special Conditions and Actions

Particular characters used before Procmail recipe conditions and actions change the way they are interpreted.

The following characters may be used after the `*` character at the beginning of a recipe's condition line:

- `!` — Inverts the condition, causing a match to occur only if the condition does not match the message.
- `<` — Checks to see if the message is under the specified number of bytes.
- `>` — Checks to see if the message is over a particular number of bytes.

The following characters are used to perform special actions:

- `!` — Tells Procmail to forward the message to the specified email addresses

- `$` — Refers to a variable set earlier in the `rc` file. This is usually used to set a common mailbox that will be referred to by various recipes.
- `|` — The pipe character tells Procmail to start a specific program to deal with this message.
- `{ and }` — Constructs a nesting block, used to contain additional recipes to apply to matching messages.

If no special character is used at the beginning of the action line, then Procmail assumes that the action line is specifying a mailbox where the message should be written.

15.5.2.5. Recipe Examples

Procmail is an extremely flexible program, allowing you to match messages with very specific conditions and then perform detailed actions on them. As a result of this flexibility, however, composing a Procmail recipe from scratch to achieve a certain goal can be difficult for new users.

The best way to develop the skills to build Procmail recipe conditions stems from a strong understanding of regular expressions combined with looking at many examples built by others. The following very basic examples exist to serve as a demonstration of the structure of Procmail recipes and can provide the foundation for more intricate constructions.

The most basic recipes does not even contain conditions, as is illustrated in the following example.

```
:0:
new-mail.spool
```

The first line starts the recipe by specifying that a local lockfile is to be created but does not specify a name, leaving Procmail to use the destination filename and the `LOCKEXT` to name it. No condition is specified, so every message will match this recipe and, therefore, will be placed in the single spool file called `new-mail.spool`, located within the directory specified by the `MAILDIR` environment variable. An MUA can then view the messages in this file.

This basic recipe could go at the end of all `rc` files to direct messages to a default location. A more complicated example might grab messages from a particular email address and throw them away, as can be seen in this example.

```
:0
* ^From: spammer@domain.com
/dev/null
```

With this example, any messages sent by `spammer@domain.com` are immediately moved to `/dev/null`, deleting them.

Caution

Be very careful that a rule is working correctly before moving messages matching it to `/dev/null`, which is a permanent deletion. If your recipe conditions inadvertently catch unintended messages, you will not even know you are missing those messages unless the sender tells you.

A better solution is to point the recipe's action to a special mailbox that you can check from time to time in order to look for *false positives*, or messages that inadvertently matched the conditions. Once you are satisfied that no messages are accidentally being matched, you can delete the mailbox and direct the action to send the messages to `/dev/null`.

Procmail is primarily used as a filter for email, automatically placing it in the right place so that you do not have to sort it manually. The following recipe in grabs email sent from a particular mailing list and puts in the correct folder for you.

15.6.2. Secure Email Servers

Offering SSL encryption to IMAP and POP users on the email server is almost as easy. Red Hat Linux also includes the `stunnel` package, which is an SSL encryption wrapper that wraps around standard, non-secure network traffic for certain services and prevents interceptors from being able to "sniff" the communication between client and server.

The `stunnel` program uses external SSL libraries, such as the OpenSSL libraries included with Red Hat Linux, to provide strong cryptography and protect your connections. You can apply to a *Certificate Authority (CA)* for an SSL certificate, or you can create a self-signed certificate to provide the benefit of the SSL encrypted communication.

To create a self-signed SSL certificate, change to the `/usr/share/ssl/certs/` directory, type the `make stunnel.pem` command, and answer the questions. Then, use `stunnel` to start the mail daemon that you wish to use.

For example, the following command could be used to start the IMAP server included with Red Hat Linux:

```
/usr/sbin/stunnel -d 993 -l /usr/sbin/imapd imapd
```

You should now be able to open an IMAP email client and connect to your email server using SSL encryption. Of course, you will probably want to go a step further and configure your `stunnel`-wrapped IMAP server to automatically start up at the correct runlevels.

For more information about how to use `stunnel`, read the `stunnel` man page or refer to the documents in the `/usr/share/doc/stunnel-<version-number>` directory.

Alternatively, the `imap` package bundled with Red Hat Linux contains the ability to provide SSL encryption on its own without `stunnel`. For secure IMAP connections, create the SSL certificate by changing to the `/usr/share/ssl/certs/` directory and running the `make imapd.pem` command. Then, set the `imapd` service to start at the proper runlevels.

You can also use the `ipop3` package bundled with Red Hat Linux to provide SSL encryption on its own without `stunnel`.

15.7. Additional Resources

Many users initially find email programs difficult to configure, primarily due to the large number of options available. Below is a list of additional documentation to help you properly configure your mail applications.

15.7.1. Installed Documentation

- Information about how to configure Sendmail is included with the `sendmail` and `sendmail-cf` packages.
 - `/usr/share/doc/sendmail/README.cf` — Contains information on `m4`, file locations for Sendmail, supported mailers, how to access enhanced features, and more.
 - `/usr/share/doc/sendmail/README` — Contains information on the Sendmail directory structure, IDENT protocol support, details on directory permissions, and the common problems these permissions can cause if misconfigured.

In addition, the `sendmail` and `aliases` man pages contain helpful information covering various Sendmail options and the proper configuration of the Sendmail `/etc/mail/aliases` file, respectively.

- `/usr/share/doc/fetchmail-<version-number>` — Contains a full list of Fetchmail features in the `FEATURES` file and an introductory `FAQ` document.
- `/usr/share/doc/procmail-<version-number>` — Contains a `README` file that provides an overview of Procmail, a `FEATURES` file that explores every program feature, and an `FAQ` file with answers to many common configuration questions.

When learning how Procmail works and creating new recipes, the following Procmail man pages are invaluable:

- `procmail` — Provides an overview of how Procmail works and the steps involved with filtering email.
- `procmailrc` — Explains the `rc` file format used to construct recipes.
- `procmailex` — Gives a number of useful, real-world examples of Procmail recipes.
- `procmailsc` — Explains the weighted scoring technique used by Procmail to see if a particular recipe matches a certain message.

15.7.2. Useful Websites

- <http://www.redhat.com/mirrors/LDP/HOWTO/Mail-Administrator-HOWTO.html> — Provides an overview of how email works and examines possible email solutions and configurations on the client and server sides.
- <http://www.redhat.com/mirrors/LDP/HOWTO/Mail-User-HOWTO> — Looks at email from the user's perspective, investigates various popular email client applications and gives an introduction to topics such as aliases, forwarding, auto-replying, mailing lists, mail filters, and spam.
- <http://www.redhat.com/mirrors/LDP/HOWTO/mini/Secure-POP+SSH.html> — Demonstrates a way to retrieve POP email using SSH with port forwarding, so that your email passwords and messages will be transferred securely.
- <http://www.sendmail.net> — Contains news, interviews, and articles concerning Sendmail, including an expanded view of the many options available.
- <http://www.sendmail.org> — Offers a thorough technical breakdown of Sendmail features and configuration examples.
- <http://tuxedo.org/~esr/fetchmail> — The home page for Fetchmail, featuring an online manual, and a thorough `FAQ`.
- <http://www.procmail.org> — The home page for Procmail, with links to assorted mailing lists dedicated to Procmail as well as various `FAQ` documents.
- <http://www.ling.helsinki.fi/users/rierikso/procmail/mini-faq.html> — An excellent Procmail `FAQ`, with troubleshooting tips and details about file locking and the use of wildcard characters.
- <http://www.uwasa.fi/~ts/info/proctips.html> — Points out dozens of tips that make using Procmail in various situations much easier, including how to test `.procmailrc` files and use Procmail scoring to decide if a particular action should be taken.

15.7.3. Related Books

- *Sendmail* by Bryan Costales with Eric Allman et al; O'Reilly & Associates — A good Sendmail reference written with the assistance of the original creator of Delivermail and Sendmail.

- *Removing the Spam: Email Processing and Filtering* by Geoff Mulligan; Addison-Wesley Publishing Company — A volume that looks at various methods used by email administrators that use established tools, such as Sendmail and Procmail, to manage spam problems.
- *Internet Email Protocols: A Developer's Guide* by Kevin Johnson; Addison-Wesley Publishing Company — Provides a very thorough review of major email protocols and the security they provide.
- *Managing IMAP* by Dianna Mullet and Kevin Mullet; O'Reilly & Associates — Details the steps required to configure an IMAP server.

Berkeley Internet Name Domain (BIND)

Today, the Internet and almost all local networks depend upon a working and reliable *Domain Name Service (DNS)*, which is used to resolve names of systems into IP addresses and vice versa.

In order to facilitate DNS on your network, a *nameserver* is required to translate these names into the IP addresses necessary to make the connection. In addition, a nameserver can translate IP addresses back into a system's name, commonly called a *reverse lookup*.

This chapter discusses BIND, the structure of its configuration files, and how it may be locally or remotely administered.

For instructions on configuring BIND using the graphical **Bind Configuration Tool** (`redhat-config-bind`), please see the chapter called *BIND Configuration* in the *Official Red Hat Linux Customization Guide*.

Warning

If you use the **Bind Configuration Tool**, you should not manually edit any BIND configuration files because all changes will be overwritten the next time you use the **Bind Configuration Tool**.

16.1. Introduction to DNS and BIND

Systems using IP networks must know the IP address of a remote machine in order to connect to it. However, most users prefer to use the name of a machine, called a *hostname* or a *fully qualified domain name (FQDN)*, when connecting to it.

Use of fully qualified domain names also have advantages for system administrators. They allow administrators to flexibility in changing the IP addresses for individual machines without effecting name-based queries to the machines. Conversely, administrators can shuffle which machines handle a name-based query in a way transparent to the user.

The service that facilitates this is called DNS, and it is normally implemented using centralized servers that are authoritative for some domains and refer to other DNS servers for other domains.

DNS under Linux is made possible through the use of a *nameserver* daemon that performs the IP/hostname translation. A client application will request information from the nameserver, usually connecting to it on the server's port 53. The nameserver will attempt to resolve the FQDN based on its resolver library, which may contain authoritative information about the host requested or cached data about that name from an earlier query. If the nameserver does not already have the answer in its resolver library, it will turn to other nameservers, called *root nameservers*, to determine which nameservers are authoritative for the FQDN in question. Then, with that information, it will query the authoritative nameservers for that name to determine the IP address. If performing a reverse lookup, the same procedure is used, except the query is made with an unknown IP address rather than a name.

16.1.1. Zones

On the Internet, the FQDN of a host can be broken down into different sections, and these sections are organized in a hierarchy much like a tree, with a main trunk, primary branches, secondary branches, and so forth. Consider the following FQDN:

```
bill.sales.domain.com
```

When looking at how a FQDN is resolved to find the IP address that relates to a particular system, you must read the name from right to left, with each level of the hierarchy divided by dots (.). In this example, the `com` defines the *top level domain* for this FQDN. The `domain` name is a sub-domain under `com`, with `sales` as a sub-domain under `domain`. The name furthest left in a FQDN is the hostname, identifying a particular machine.

Except for the hostname, every section is called a *zone*, which defines a particular namespace. A *namespace* controls the naming of the sub-domains to its left. While this example only contains two sub-domains, a FQDN must contain at least one sub-domain but may include many more, depending upon how the namespace is organized.

Zones are defined on authoritative nameservers through the use of *zone files*, which describe the namespace of that zone, the mail servers to be used for a particular domain or sub-domain, and more. Zone files are stored on *primary nameservers* (also called *master nameservers*), which are truly authoritative and where changes are made to the files, and *secondary nameservers* (also called *slave nameservers*), which receive their zone files from the primary nameservers. Any nameserver can be a primary and secondary nameserver for different zones at the same time, and they may also be considered authoritative for multiple zones. It all depends on the nameserver's configuration.

16.1.2. Types of Nameservers

There are four primary nameserver configuration types:

- *master* — Stores original and authoritative zone records for a certain namespace, answering questions from other nameservers searching for answers concerning that namespace.
- *slave* — Also answers queries from other nameservers concerning namespaces for which it is considered an authority. However, slave nameservers get their namespace information from master nameservers via a *zone transfer*, where the slave sends the master a `NOTIFY` request for a particular zone and the master responds with the information, if the slave is authorized to receive the transfer.
- *caching-only* — Offers name to IP resolution services but is not authoritative for any zones. Answers for all resolutions are usually cached in a database stored in memory for a fixed period of time, usually specified by the retrieved zone record, for quicker resolution for other DNS clients after the first resolution.
- *forwarding* — Forwards requests to a specific list of nameservers to be resolved. If none of the specified nameservers can perform the resolution, the process stops and the resolution fails.

A nameserver may be one or more of these types. For example, a nameserver can be a master for some zones, a slave for others, and only offer forwarding resolution.

16.1.3. BIND as a Nameserver

Red Hat Linux includes BIND, which is a very popular, powerful, open source nameserver. BIND uses the `named` daemon to provide name resolution services.

BIND version 9 also includes a utility called `/usr/sbin/rndc` which allows the administration of the running `named` daemon. More information about `rndc` can be found in Section 16.3.

16.2. BIND Configuration Files

The BIND nameserver `named` server configuration is `/etc/named.conf`. All zone files are placed in the `/var/named/` directory.

The `/etc/named.conf` file must be free of errors in order for `named` to start. While some erroneous options are not considered critical enough to stop the server, any errors in the statements themselves will prevent the `named` service from starting.

Warning

Do *not* manually edit the `/etc/named.conf` file or any files in the `/var/named/` directory if you are using the **Bind Configuration Tool**. Any manual changes to those files will be overwritten the next time the **Bind Configuration Tool** is used.

16.2.1. `/etc/named.conf`

The `/etc/named.conf` file is a collection of statements using nested options placed in ellipses `{ }`. A sample `/etc/named.conf` file is organized similar to this:

```
<statement-1> [ "<statement-1-name>" ] [ <statement-1-class> ] {
    <option-1>;
    <option-2>;
    <option-N>;
};

<statement-2> [ "<statement-2-name>" ] [ <statement-2-class> ] {
    <option-1>;
    <option-2>;
    <option-N>;
};

<statement-N> [ "<statement-N-name>" ] [ <statement-N-class> ] {
    <option-1>;
    <option-2>;
    <option-N>;
};
```

The `<statement-N-name>` is only needed with `acl`, `include`, `server`, `view`, and `zone` statements. The `<statement-N-class>` may only be specified with the `zone` statement.

The following is a list of valid comment tags you may use within `/etc/named.conf`:

- `//` — Use at the beginning of a line comment that line.
- `#` — Use at the beginning of a line comment that line.
- `/*` and `*/` — Enclose text in these tags to create a block comment.

The following statements may be used in `/etc/named.conf`:

- `acl <acl-name>4` — Configures an access control list of IP addresses to be allowed or disallowed certain `named` services. Most of the time, individual IP addresses or IP network notation (such as `10.0.1.0/24`) is used identify the exact IP addresses.

A few access control lists are already defined, so you do not have to configure an `acl` statement to define them:

- `any` — Matches every IP address.
- `localhost` — Matches any IP address in use by the local system.
- `localnets` — Matches any IP address on any network to which the local system is connected.
- `none` — Matches no IP addresses.

When used with other `/etc/named.conf` statements and their options, `acl` statements can be very useful in ensuring the proper use of your BIND nameserver as in this example:

```
acl black-hats {
    10.0.2.0/24;
    192.168.0.0/24;
};

acl red-hats {
    10.0.1.0/24;
};

options {
    blackhole { black-hats; };
    allow-query { red-hats; };
    allow-recursion { red-hats; };
}
```

This `named.conf` contains two access control lists `black-hats` and `red-hats`.

- `controls` — Configures various security requirements necessary to use the `rndc` command to administer the `named` service.

See Section 16.3.1.1 to see how the `controls` statement should look, including various options that may only be used with it.

- `include "<file-name>"` — Includes the specified file within the current configuration file, allowing sensitive configuration data (such as `keys`) to be placed in a separate file with permissions that prevent non-privileged users from reading it.
- `key "<key-name>"` — Defines a particular key by name. Keys are used to authenticate various actions, such as secure updates or the use of the `rndc` command. Two options are used with `key`:
 - `algorithm <algorithm-name>` — The type of algorithm used, such as `dsa` or `hmac-md5`.
 - `secret "<key-value>"` — The encrypted key.

See Section 16.3.1.2 for instruction on how to write a `key` statement.

- `logging` — Allows for the use of multiple types of logs, called *channels*. By using the `channel` option within the `logging` statement, a customized type of log, with its own file name (`file`), size limit (`size`), versioning (`version`), and level of importance (`severity`), can be constructed. Once a customized channel has been defined, a `category` option is used to categorize the channel and begin logging when `named` is restarted.

By default, `named` logs standard messages to the `syslog` daemon, which places them in `/var/log/messages`. This occurs because several standard channels are built into BIND with various severity levels, such as one that handles informational logging messages (`default_syslog`) and another that specifically handles debugging messages (`default_debug`). A default category, called `default`, uses the built-in channels to do normal logging without any special configuration.

Customizing the logging process can be a very detailed process and is beyond the scope of this chapter. For information on creating custom BIND logs, see the *BIND 9 Administrator Reference Manual*.

- `options` — Assigns values to many assorted options, including the use of forwarders, the location of the `named` working directory, the names of the various files, and much more.

The following options are among the most commonly used:

- `allow-query` — Specifies which hosts are allowed to query this nameserver. By default, all hosts are allowed to query. An access control list or collection of IP addresses or networks may be used here to only allow particular hosts to query the nameserver.

- `allow-recursion` — Similar to `allow-query`, except it applies to recursive queries. By default, all hosts are allowed to perform recursive queries on the nameserver.
- `directory` — Changes the `named` working directory to something other than the default, `/var/named`.
- `forward` — Controls how forwarding occurs, if the `forwarders` option contains valid IP addresses designating where to send requests.

If the `first` option is used, then the nameservers specified in the `forwarders` option are queried first for the information, and if they do not have it, `named` will attempt the resolution itself.

If the `only` option is used, `named` will not attempt the resolution itself if the `forwarders` are not successful.

- `forwarders` — Specifies a list of nameservers where requests should be forwarded for resolution.
- `listen-on` — Specifies the network interface that `named` will use to listen for queries. By default, all interfaces are used.

This option is useful if you have more than one network interface and would like to limit the systems that can make requests of your nameserver. For example, if you have a machine serving as a gateway and a nameserver, and you would like to block any requests except those that originate from your private network, your `listen-on` option might look like this:

```
options {
    listen-on { 10.0.1.1; };
};
```

In this way, only requests that arrive from the network interface serving the private network (10.0.1.1) will be accepted.

- `notify` — Controls whether `named` notifies the slave servers when a zone is updated. The default is `yes`, but you can set this to `no`, to prevent slaves from being notified, or `explicit`, to only notify servers in an `also-notify` list.
- `pid-file` — Allows you to specify the location of the process ID file created by `named` when it starts.
- `statistics-file` — Allows you to specify the location of where the statistics file is written. By default, `named` statistics are saved in `/var/named/named.stats`.

Dozens of other options are also available, many of which rely upon one another to work properly. See the *BIND 9 Administrator Reference Manual* for more details.

- `server` — Defines particular options that affect how `named` should act toward remote nameservers, especially regarding notifications and zone transfers.

The `transfer-format` option controls whether one resource record is sent with each message (`one-answer`) or multiple resource records are sent with each message (`many-answers`). While `many-answers` is more efficient, only newer BIND nameservers understand it.

- `trusted-keys` — Contains assorted public keys used for DNSSEC. See Section 16.4.3 for an introduction to BIND security.
- `view "<view-name>"` — Creates special views that respond with a particular type of information depending upon the host contacting the nameserver. This allows some hosts to receive one answer regarding a particular zone while other hosts receive totally different information. Alternatively, certain zones may only be made available to particular trusted hosts while non-trusted hosts can only make queries for other zones.

Multiple views may be used, so long as their names are unique. The `match-clients` option specifies the IP addresses that apply to a particular view. Any `option` statements may also be used within a view, overriding the global options already configured for `named`. Most `view` statements contain multiple `zone` statements that apply to the `match-clients` list. The order in which `view`

statements are listed is important, as the first `view` statement that matches a particular client's IP address is used.

See Section 16.4.2 for more information about the `view` statement.

- `zone "<zone-name>"` — Specifies particular zones for which this nameserver is authoritative. The `zone` statement is primarily used to specify the file containing the zone's configuration and pass certain options about that zone to `named` that override other global `option` statements used in `/etc/named.conf`.

The name of the zone is important, as it is the default value assigned to the `$ORIGIN` directive used in the zone file and is appended to non-FQDNs. So, for example, if this `zone` statement defines the namespace for `domain.com`, you should use `domain.com` as the `<zone-name>` so it will be placed at the end of hostnames used in the zone file.

The most common `zone` statement options include:

- `allow-query` — Specifies the clients that are allowed to request information about this zone. The default is to allow all query requests.
- `allow-transfer` — Specifies the slave servers that are allowed to request a transfer of the zone's information. The default is to allow all transfer requests.
- `allow-update` — Specifies the hosts that are allowed to dynamically update information in their zone. The default is to deny all dynamic update requests.

Be very careful about allowing hosts to update information about their zone. Do not enable this option unless the host specified is completely trusted. It is generally better to have an administrator manually update the zone's records and reload the `named` service, if possible.

- `file` — Specifies the name of the file in the `named` working directory that contains the zone's configuration data. The default is `/var/named`.
- `masters` — Used if the zone is defined as a slave type. The `masters` option tells a slave's `named` the IP addresses from which to request authoritative zone information.
- `notify` — Works in a similar manner to the `notify` option used with the `option` statement.
- `type` — Defines the type of zone. The following types may be used:
 - `forward` — Tells the nameserver to forward all requests for information about this zone to other nameservers.
 - `hint` — A special type of zone that is used to point to the root nameservers, which are used to resolve queries when a zone is not otherwise known. You should not need to configure a hint zone beyond the default in `/etc/named.conf`.
 - `master` — Designates this nameserver as authoritative for this zone. A zone should be set as the `master` type if you have the zone's configuration files on this system.
 - `slave` — Designates this nameserver as a slave server for this zone, telling `named` to request the zone's configuration files from the master nameserver's IP address for that zone.
- `zone-statistics` — Tells `named` to keep statistics concerning this zone, writing them to either the default location (`/var/named/named.stats`) or the place specially designated by the `statistics-file` option in the `server` statement, if it exists.

16.2.1.1. Sample Zone Statements

Most changes to the `/etc/named.conf` file of a master or slave nameserver involves adding, modifying, or deleting `zone` statements. While these `zone` statements can contain many options, most

nameservers use only few of them. The following `zone` statements are very basic examples that can be used in a master-slave nameserver relationship.

The following is an example of a `zone` statement for the primary nameserver hosting `domain.com`:

```
zone "domain.com" IN {
    type master;
    file "domain.com.zone";
    allow-update { none; };
};
```

In the statement, the zone is identified as `domain.com`, the type is set to `master`, and the `named` service is instructed to read the `/var/named/domain.com.zone` file. It also tells `named` not to allow by any other hosts to update.

A slave server's `zone` statement for `domain.com` looks slightly different from the previous example. For a slave server, the type is set to `slave` and in place of the `allow-update` line is a directive telling `named` the IP address of the master server.

A slave server's `zone` statement for `domain.com` may look like this:

```
zone "domain.com" {
    type slave;
    file "domain.com.zone";
    masters { 192.168.0.1; };
};
```

This `zone` statement tells `named` on the slave server to look for the master server at the `192.168.0.1` IP address to find information for the `domain.com` zone. The information the slave server receives from the master server is saved in the `/var/named/domain.com.zone` file.

16.2.2. Zone Files

Zone files, which contain information about a particular namespace, are stored in the `named` working directory. By default, this is `/var/named`. Each zone file is named according to the `file` option data in the `zone` statement, usually in a way that relates to the domain in question and identifies the file as containing zone data, such as `example.com.zone`.

Each zone file may contain directives and resource records. *Directives* tell the nameserver to do a certain thing or apply a special setting to the zone. *Resource records* define the parameters of the zone, assigning an identity within the zone's namespace to particular systems. Directives are optional, but resource records are required to provide nameservice to that zone. All directives and resource records should go on their own lines.

Comments can be placed after semicolon characters (`;`) in zone files.

16.2.2.1. Zone File Directives

Directives are identified by the leading `$` character before the name of the directive and usually placed at the top of the zone file.

The following directives are the most commonly used:

- `$INCLUDE` — Tells `named` to include another zone file in this zone file at the place where the directive is used. This allows additional zone settings to be stored apart from the main zone file.
- `$ORIGIN` — Sets the domain name to be appended to any unqualified records, such as those that only specify the host and nothing more.

For example, a zone file may contain the following line:

```
$ORIGIN domain.com
```

At this point, any names that are used in resource records and do not end in a trailing dot (.) will have this domain name added to them. So, in other words, when the zone record is read by the nameserver, the first line below will be interpreted as the second line:

```
ftp                IN      CNAME   server1
ftp.domain.com.   IN      CNAME   server1.domain.com.
```

Note

The use of the `$ORIGIN` directive is unnecessary if you name the zone in `/etc/named.conf` the same as the value you would assign to `$ORIGIN`. The zone's name is used as the `$ORIGIN` directive's value by default.

- **TTL** — Sets the default *Time to Live (TTL)* value for the zone. This is the number, in seconds, given to nameservers that tells how long the zone's resource records should continue to be valid. A resource record can contain its own TTL value, which would override this directive.

Increasing this value tells remote nameservers to cache this zone's information for a longer time. This reduces the number of queries made concerning this zone, but it also lengthens the amount of time required to proliferate resource record changes.

16.2.2.2. Zone File Resource Records

Zone file resource records contain columns of data, separated by whitespace, that define the record. All zone file resource records are assigned a particular type, which designates the record's purpose. The following types of resource records are the most commonly used:

- **A** — Address record, which specifies an IP address to assign to a name, as in this example:

```
<host>           IN      A       <IP-address>
```

If the `<host>` value is omitted, then an `A` record points to a default IP address for the top of the namespace. This system will be the target of all non-FQDN requests.

Consider the following `A` record examples for the `domain.com` zone file:

```
                IN      A       10.0.1.3
server1         IN      A       10.0.1.5
```

Requests for `domain.com` are pointed to 10.0.1.3, while requests for `server1.domain.com` are pointed to 10.0.1.5.

- **CNAME** — Canonical name record, maps one name to another: an alias.

The next example tells `named` that any requests sent to the `<alias-name>` will point to the host, `<real-name>`. `CNAME` records are most commonly used to point services that use a common naming scheme to the correct host.

```
<alias-name>     IN      CNAME   <real-name>
```

Consider the following example. In this set up an `A` record binds a hostname to an IP address, while a `CNAME` record points the commonly used `www` hostname to it.

```
server1         IN      A       10.0.1.5
www             IN      CNAME   server1
```

- **MX** — Mail eXchange record, which tells where mail sent to a particular namespace controlled by this zone should go.

```
                IN      MX      <preference-value> <email-server-name>
```

In this example, the `<preference-value>` allows you to numerically rank the email servers you would prefer to receive email for this namespace, giving preference to some email systems

over others. The `MX` resource record with the lowest `<preference-value>` is preferred over the others, but you can set multiple email servers with the same value to distribute email traffic between them.

The `<email-server-name>` may be a hostname or FQDN, as long as it points to the correct system.

```
IN      MX      10      mail.domain.com.
IN      MX      20      mail2.domain.com.
```

In this example, the first `mail.domain.com` email server is preferred to the `mail2.domain.com` email server when receiving email destined for the `domain.com` domain.

- **NS** — NameServer record, which announces the authoritative nameservers for a particular zone.

This is an example of an NS record:

```
IN      NS      <nameserver-name>
```

The `<nameserver-name>` should be a FQDN.

Next, two nameservers are listed as authoritative for the domain. It is not important whether these nameservers are slaves or if one is a master; they are both still considered authoritative.

```
IN      NS      dns1.domain.com.
IN      NS      dns2.domain.com.
```

- **PTR** — PoinTeR record, designed to point to another part of the namespace.

`PTR` records are primarily used for reverse name resolution, as they point IP addresses back to a particular name. See Section 16.2.2.4 for more examples of `PTR` records in use.

- **SOA** — Start Of Authority record, proclaims important authoritative information about a namespace to the nameserver.

Located after the directives, an `SOA` resource record is the first resource record in a zone file.

The following example shows the basic structure of an `SOA` record:

```
@      IN      SOA      <primary-name-server>  <hostmaster-email> (
<serial-number>
<time-to-refresh>
<time-to-retry>
<time-to-expire>
<minimum-TTL> )
```

The `@` symbol places the `$ORIGIN` directive (or the zone's name, if the `$ORIGIN` directive is not set) as the namespace being defined by this `SOA` resource record. The primary nameserver that is authoritative for this domain is used for the `<primary-name-server>`, and the email of the person to contact about this namespace is substituted for the `<hostmaster-email>`.

The `<serial-number>` is incremented every time you change the zone file so that `named` will know that it should reload this zone. The `<time-to-refresh>` tells any slave servers how long to wait before asking the master nameserver if any changes have been made to the zone. The `<serial-number>` value is used by the slave to determine if it is using outdated zone data and should refresh it.

The `<time-to-retry>` tells the slave nameserver the interval to wait before issuing another refresh request, if the master nameserver is not answering. If the master has not replied to a refresh request before the `<time-to-expire>` elapses, the slave stops responding as an authority for requests concerning that namespace.

The `<minimum-TTL>` requests that other nameservers cache the zone's information for at least this amount of time (in seconds).

With BIND, all times refer to seconds. However, you can also use abbreviations for other units of time other than seconds, such as minutes (`M`), hours (`H`), days (`D`), and weeks (`W`). The table in Table 16-1 shows an amount of time in seconds and the equivalent time in another format.

Seconds	Other Time Units
60	1M
1800	30M
3600	1H
10800	3H
21600	6H
43200	12H
86400	1D
259200	3D
604800	1W

Table 16-1. Seconds compared to other time units

The following example illustrates the form an SOA resource record might take when it is configured with real values.

```
@      IN      SOA      dns1.domain.com.      hostmaster.domain.com. (
                2001062501 ; serial
                21600      ; refresh after 6 hours
                3600      ; retry after 1 hour
                604800    ; expire after 1 week
                86400    ) ; minimum TTL of 1 day
```

16.2.2.3. Zone File Examples

Seen individually, the directives and resource records can be difficult to grasp. However, everything makes much more sense when it is placed together in a common file. The next example shows a very basic zone file.

```
$ORIGIN domain.com
$TTL 86400
@      IN      SOA      dns1.domain.com.      hostmaster.domain.com. (
                2001062501 ; serial
                21600      ; refresh after 6 hours
                3600      ; retry after 1 hour
                604800    ; expire after 1 week
                86400    ) ; minimum TTL of 1 day

      IN      NS       dns1.domain.com.
      IN      NS       dns2.domain.com.

      IN      MX       10    mail.domain.com.
      IN      MX       20    mail2.domain.com.

      IN      A        10.0.1.5

server1  IN      A        10.0.1.5
server2  IN      A        10.0.1.7
dns1     IN      A        10.0.1.2
dns2     IN      A        10.0.1.3

ftp      IN      CNAME    server1
mail     IN      CNAME    server1
mail2    IN      CNAME    server2
www      IN      CNAME    server2
```

In this example, standard directives and SOA values are used. The authoritative nameservers are set to be `dns1.domain.com` and `dns2.domain.com`, which have A records that tie them to `10.0.1.2` and `10.0.1.3`, respectively.

The email servers configured with the MX records point to `server1` and `server2` via CNAME records. Since the `server1` and `server2` names do not end in a trailing dot (`.`), the `$ORIGIN` domain is placed after them, expanding them to `server1.domain.com` and `server2.domain.com`. Through the related A resource records, their IP addresses can be determined.

The popular FTP and Web services, available at the standard `ftp.domain.com` and `www.domain.com` names, are pointed toward machines providing the appropriate services for those names using CNAME records.

16.2.2.4. Reverse Name Resolution Zone Files

A reverse name resolution zone file is used to translate an IP address in a particular namespace into a FQDN. It looks very similar to a standard zone file, except that PTR resource records are used to link the IP addresses to a certain system's name.

A PTR record looks similar to this:

```
<last-IP-digit>      IN      PTR      <FQDN-of-system>
```

The `<last-IP-digit>` relates to the last number in an IP address that should point to a particular system's FQDN.

In the follow example, IP addresses `10.0.1.20` through `10.0.1.25` are pointed to corresponding FQDNs.

```
$ORIGIN 1.0.10.in-addr.arpa
$TTL 86400
@      IN      SOA      dns1.domain.com.      hostmaster.domain.com. (
                2001062501 ; serial
                21600      ; refresh after 6 hours
                3600      ; retry after 1 hour
                604800    ; expire after 1 week
                86400 )    ; minimum TTL of 1 day

      IN      NS       dns1.domain.com.
      IN      NS       dns2.domain.com.

20    IN      PTR      alice.domain.com.
21    IN      PTR      betty.domain.com.
22    IN      PTR      charlie.domain.com.
23    IN      PTR      doug.domain.com.
24    IN      PTR      ernest.domain.com.
25    IN      PTR      fanny.domain.com.
```

This zone file would be called into service with a `zone` statement in the `/etc/named.conf` file that looks similar to this:

```
zone "1.0.10.in-addr.arpa" IN {
    type master;
    file "domain.com.rr.zone";
    allow-update { none; };
};
```

There is very little difference between this example and a standard `zone` statement, except for how the zone is named. Note that a reverse name resolution zone requires the first three blocks of the IP

address to be reversed and ".in-addr.arpa" to be included after them. This allows the single block of IP numbers used in the reverse name resolution zone file to be correctly attached with this zone.

16.3. Using rndc

BIND includes a utility called `rndc` which allows you to use command line statements to administer the `named` daemon, locally, or remotely. The `rndc` program uses the `/etc/rndc.conf` file for its configuration options, which can be overridden with command line options.

In order to prevent unauthorized users on other systems from controlling BIND on your server, a shared secret key method is used to explicitly grant privileges to particular hosts. In order for `rndc` to issue commands to any `named`, even on a local machine, the keys used in `/etc/named.conf` and `/etc/rndc.conf` must match.

16.3.1. Configuring rndc

Before attempting to use the `rndc` command, verify that the proper configuration lines are in place in the necessary files. Most likely, your configuration files are not properly set if you run `rndc` and see a message that states:

```
rndc: connect: connection refused
```

16.3.1.1. rndc and /etc/named.conf

In order for `rndc` to be allowed to connect to your `named` service, you must have a `controls` statement in your `/etc/named.conf` file when `named` starts. The sample `controls` statement shown in the next example will allow you to execute `rndc` commands locally.

```
controls {
    inet 127.0.0.1 allow { localhost; } keys { <key-name>; };
};
```

This statement tells `named` to listen on the default TCP port 953 of the loopback address and allow `rndc` commands coming from the `localhost`, if the proper key is given. The `<key-name>` relates to the `key` statement, which is also in the `/etc/named.conf` file. The next example illustrates a sample `key` statement.

```
key "<key-name>" {
    algorithm hmac-md5;
    secret "<key-value>";
};
```

In this case, the `<key-value>` is a HMAC-MD5 key. You can generate your own HMAC-MD5 keys with the following command:

```
dnssec-keygen -a hmac-md5 -b <bit-length> -n HOST <key-file-name>
```

A key with at least a 256-bit length is good idea. The actual key that should be placed in the `<key-value>` area can found in the `<key-file-name>`.

The name of the key used in `/etc/named.conf` should be something other than `key`.

16.3.1.2. `/etc/rndc.conf`

You need to add the following lines to `/etc/rndc.conf` if `rndc` is to automatically use the keys specified in `/etc/named.conf`. This is done with an `options` statement:

```
options {
    default-server    localhost;
    default-key       "<key-name>";
};
```

This command sets a global default key, but the `rndc` command can also use different keys for particular servers, as in the following example:

```
server localhost {
    key "<key-name>";
};
```

However, this `server` statement is only really helpful if you connect to multiple servers with `rndc`.

The `key` is the most important statement in `/etc/rndc.conf`.

```
key "<key-name>" {
    algorithm hmac-md5;
    secret "<key-value>";
};
```

The `<key-name>` and `<key-value>` should be exactly the same as their settings in `/etc/named.conf`.

To test all of the settings, try the `rndc reload` command. You should see response similar to this:

```
rndc: reload command successful
```

If the command was not successful, carefully look over the `/etc/named.conf` and `/etc/rndc.conf` files and look for errors.

16.3.2. `rndc` Command Line Options

An `rndc` command takes the following form:

```
rndc <options> <command> <command-options>
```

The `<options>` area is not required, and you do not have to use `<command-options>` unless the command requires them.

When executing `rndc` on a properly configured localhost, the following commands are available:

- `halt` — Stops the `named` service immediately.
- `querylog` — Turns on logging of all queries made by clients to this nameserver.
- `refresh` — Refreshes the nameserver's database.
- `reload` — Tells the nameserver to reload the zone files but keep all other previously cached responses. This allows you to make changes to zone files and have them take effect on your master and slave servers without losing all stored name resolutions.

If your changes only affected a particular zone, you can tell `named` to only reload that one zone. Type the name of the zone after the `reload` command.

- `stats` — Dumps the current named stats to the `/var/named/named.stats` file.
- `stop` — Stops the server gracefully, saving any dynamic update and IXFR data before exiting.

Occasionally, you may want to override the default settings in the `/etc/rndc.conf` file. The following options are available:

- `-c <configuration-file>` — Tells `rndc` to use a configuration file other than the default `/etc/rndc.conf`.
- `-p <port-number>` — Specifies a different port number to use for the `rndc` connection other than the default 953.
- `-s <server>` — Tells `rndc` to send the command to a server other than the `default-server` option in `/etc/rndc.conf` file.
In order for this to work, you must have configured the other `named` service to accept commands from your host and have the key for that nameservice.
- `-y <key-name>` — Allows you to specify a key other than the `default-key` option in `/etc/rndc.conf` file.

Additional information about these options can be found in the `rndc` man page.

16.4. Advanced Features of BIND

Most BIND implementations only use `named` to provide name resolution services or to act as an authority for a particular domain or sub-domain. However, BIND version 9 has a number of advanced features that, when properly configured, allow for a more secure and efficient DNS service.

Caution

Some of these advanced features, such as DNSSEC, TSIG, and IXFR, should only be used in network environments with nameservers that support the features. If your network environment includes non-BIND or older BIND nameservers, check to see if a particular advanced feature is available before attempting to use it.

Do not assume another type of nameserver supports all of these features, as many do not.

All of the features discussed here are discussed in greater detail in the *BIND 9 Administrator Reference Manual*. See Section 16.6 for places to find this manual.

16.4.1. DNS Protocol Enhancements

BIND supports *Incremental Zone Transfers (IXFR)*, where slave nameserver will only download the updated portions of a zone modified on a master nameserver. The standard transfer AXFR process requires that the entire zone be transferred to each slave nameserver for even the smallest change. For very popular domains with very lengthy zone files and many slave nameservers, IXFR makes the notification and update process much less resource intensive.

Note that IXFR is only available if you are also using *dynamic updating* to make changes to master zone records. If you are manually editing zone files to make changes, AXFR will be used. More information on dynamic updating is available in the *BIND 9 Administrator Reference Manual*.

16.4.2. Multiple Views

Through the use of the `view` statement in `/etc/named.conf`, BIND allows you to configure a nameserver to answer queries for some clients in a different way than it answers them for others.

This is primarily used to deny particular types of DNS queries from clients outside of your network, while allowing those same queries from clients on the local network.

The `view` statement uses the `match-clients` option to match IP addresses or entire networks and give them special options and zone data.

16.4.3. Security

BIND supports a number of different methods to protect the updating and transfer of zones, on both master and slave nameservers:

- **DNSSEC** — Short for *DNS SECURITY*, this feature allows for zones to be cryptographically signed with a *zone key*.

In this way, the information about a specific zone can be verified as coming from a nameserver that has signed it with a particular private key, as long as the recipient has that nameserver's public key.

BIND version 9 also supports the SIG(0) public/private key method of message authentication.

- **TSIG** — Short for *Transaction SIGNatures*, a shared secret key exists on the master and slave server, verifying that a transfer from master to slave is authorized.

This feature strengthens the standard IP address-based method of transfer authorization. An attacker would not only need to have access to the IP address to transfer the zone, but they would also need to know the secret key.

BIND version 9 also support **TKEY**, which is another shared secret key method of authorizing zone transfers.

16.4.4. IP version 6

BIND version 9 can provide nameservice in IP version 6 (IPv6) environments, through the use of **A6** zone records.

If your network environment includes both IPv4 and IPv6 hosts, you should use the `lwresd` lightweight resolver daemon on your network clients. This daemon is essentially a very efficient, caching-only nameserver, which understands the new **A6** and **DNAME** records used with IPv6. See the `lwresd` man page for more information.

16.5. Common Mistakes to Avoid

It is very common for beginners to make mistakes when editing BIND configuration files or run in to initial difficulties using `named`. Be sure to avoid the following problems:

- *Make sure you increment the serial number when editing a zone file.*

If the serial number is not incremented, your master nameserver may have the correct, new information, but your slave nameservers will never be notified of the change or attempt to refresh their data of that zone.

- *Be careful to use ellipses and semi-colons correctly in the `/etc/named.conf` file.*

An omitted semi-colon or unclosed ellipse section will cause `named` to refuse to start.

- Remember to place dots (.) in zone files after all FQDNs and omit them on hostnames.

The dot denotes a fully qualified domain name. If the dot is omitted, then `named` will place the name of the zone or the `$ORIGIN` value after the name to complete it.

- If you are having problems with your firewall blocking connections from your `named` program to other nameservers, you may need to edit its configuration file.

By default, BIND version 9 uses random ports above 1024 to query other nameservers. Some firewalls, however, expect all nameservers to communicate using only port 53. You can force this behavior by adding the following line to an `options` statement in `/etc/named.conf`:

```
query-source address * port 53;
```

16.6. Additional Resources

The following sources of information will provide additional resources regarding BIND.

16.6.1. Installed Documentation

- BIND features a full-range of installed documentation covering many different topics, each placed in its own subject directory:
 - `/usr/share/doc/bind-<version-number>` — Contains a `README` file with a list of the most recent features.
 - `/usr/share/doc/bind-<version-number>/arm` — Contains HTML and SGML of the *BIND 9 Administrator Reference Manual*, which details BIND resource requirements, how to configure different types of nameservers, perform load balancing, and other advanced topics. For most new users of BIND, this is the best place to start.
 - `/usr/share/doc/bind-<version-number>/draft` — Contains assorted technical documents that look at issues related to DNS service and some methods proposed to address them.
 - `/usr/share/doc/bind-<version-number>/misc` — Contains documents designed to address specific advanced issues. Users of BIND version 8 should consult the `migration` document for specific changes they must make when moving to BIND 9. The `options` file lists all of the options implemented in BIND 9 that are used in `/etc/named.conf`.
 - `/usr/share/doc/bind-<version-number>/rfc` — Every RFC document related to BIND is in this directory.
- The following man pages are also useful:
 - `named` — Explores assorted arguments that can be used to control the BIND nameserver daemon, such as the use of an alternative configuration file and running on a different port number or as a different user.
 - `rndc` — Explains the different options available when using the `rndc` command to control a BIND nameserver.

16.6.2. Useful Websites

- <http://www.isc.org/products/BIND> — The home page of the BIND project, where you can find information concerning current releases and download a PDF version of the *BIND 9 Administrator Reference Manual*.

- <http://www.redhat.com/mirrors/LDP/HOWTO/DNS-HOWTO.html> — Covers the use of BIND as a resolving, caching nameserver or the configuration of various zone files necessary to serve as the primary nameserver for a domain.

16.6.3. Related Books

- *DNS and BIND* by Paul Albitz and Cricket Liu; O'Reilly & Associates — A popular reference that explains both common and esoteric BIND configuration options, as well as providing strategies to secure your DNS server.
- *The Concise Guide to DNS and BIND* by Nicolai Langfeldt; Que — Looks at the connection between multiple network services and BIND, with an emphasis on task-oriented, technical topics.

Network File System (NFS)

NFS (Network File System) exists to allow hosts to mount partitions on a remote system and use them as though they were local file systems. This allows files to be organized in a central location, while providing the functionality of allowing authorized users continuous access to them.

Two versions of NFS are currently in use. NFS version 2 (NFSv2), which has been around for several years, is widely supported by various operating systems. NFS version 3 (NFSv3) has several more features, including a variable file handle size and better error reporting. Red Hat Linux supports both NFSv2 and NFSv3, and uses NFSv3 by default when connecting with a server that supports it.

This chapter will focus on NFS version 2, though many of the concepts discussed also apply to version 3. Additionally, only fundamental NFS concepts and supplemental information will be provided. For specific instructions regarding the configuration and operation of NFS on client or server machines, see the chapter titled *Network File System (NFS)* in the *Official Red Hat Linux Customization Guide*.

17.1. Methodology

Linux uses a combination of kernel-level support and continuously running daemon processes to provide NFS file sharing, however, NFS support must be enabled in the Linux kernel to function. NFS uses *Remote Procedure Calls (RPC)* to route requests between clients and servers, meaning that the `portmap` service must be enabled and active at the proper runlevels for NFS communication to occur. Working with `portmap`, various other processes ensure that a particular NFS connection is allowed and may proceed without error:

- `rpc.mountd` — The running process that receives the mount request from an NFS client and checks to see if it matches with a currently exported file system.
- `rpc.nfsd` — The process that implements the user-level part of the NFS service. It works with the Linux kernel to meet the dynamic demands of NFS clients, such as providing additional server threads for NFS clients to uses.
- `rpc.lockd` — A daemon that is not necessary with modern kernels. NFS file locking is now done by the kernel. It is included with the `nfs-utils` package for users of older kernels that do not include this functionality by default.
- `rpc.statd` — Implements the *Network Status Monitor (NSM)* RPC protocol. This provides reboot notification when an NFS server is restarted without being gracefully brought down.
- `rpc.rquotad` — An RPC server that provides user quota information for remote users.

Not all of these programs are required for NFS service. The only services that must be enabled are `rpc.mountd`, `rpc.nfsd`, and `portmap`. The other daemons provide additional functionality and should only be used if your server environment requires them.

NFS version 2 uses the *User Datagram Protocol (UDP)* to provide a stateless network connection between the client and server. NFS version 3 can use UDP or TCP running over an IP. The stateless UDP connection minimizes network traffic, as the NFS server sends the client a cookie after the client is authorized to access the shared volume. This cookie is a random value stored on the server's side and is passed with along with RPC requests from the client. The NFS server can be restarted without affecting the clients and the cookie will remain intact.

NFS only performs authentication when a client system attempts to mount a remote file system. To limit access, the NFS server first employs TCP wrappers. TCP wrappers reads the `/etc/hosts.allow` and `/etc/hosts.deny` files to determine if a particular client should be

permitted or prevented access to the NFS server. For more information on configuring access controls with TCP wrappers, see Chapter 8.

After the client is allowed past TCP wrappers, the NFS server refers to its configuration file, `/etc/exports`, to determine whether the client has enough privileges to mount any of the exported file systems. After granting access, any file and directory operations are sent to the server using remote procedure calls.

Warning

NFS mount privileges are granted specifically to a client, not a user. If you grant a client machine access to an exported file system, any users of that machine will have access to the data.

When configuring the `/etc/exports` file, be extremely careful about granting read-write permissions (`rw`) to a remote host.

17.1.1. NFS and portmap

NFS relies upon remote procedure calls (RPC) to function. `portmap` is required to map RPC requests to the correct services. RPC processes notify `portmap` when they start, revealing the port number they are monitoring and the RPC program numbers they expect to serve. The client system then contacts `portmap` on the server with a particular RPC program number. `portmap` then redirects the client to the proper port number to communicate with its intended service.

Because RPC-based services rely on `portmap` to make all connections with incoming client requests, `portmap` must be available before any of these services start. If, for some reason, the `portmap` service unexpectedly quits, restart `portmap` and any services running when it was started.

The `portmap` service can be used with the host access files (`/etc/hosts.allow` and `/etc/hosts.deny`) to control which remote systems are permitted to use RPC-based services on your machine. See Chapter 8 for more information. Access control rules for `portmap` will affect all RPC-based services. Alternatively, you can specify each of the NFS RPC daemons to be affected by a particular access control rule. The man pages for `rpc.mountd` and `rpc.statd` contain information regarding the precise syntax of these rules.

17.1.1.1. portmap Status

As `portmap` provides the coordination between RPC services and the port numbers used to communicate with them, it is useful to be able to get a picture of the current RPC services using `portmap` when troubleshooting. The `rpcinfo` command shows each RPC-based service with its port number, RPC program number, version, and IP protocol type (TCP or UDP).

To make sure the proper NFS RPC-based services are enabled for `portmap`, `rpcinfo -p` can be useful:

```

program vers proto  port
100000    2    tcp    111  portmapper
100000    2    udp    111  portmapper
100024    1    udp    1024 status
100024    1    tcp    1024 status
100011    1    udp    819  rquotad
100011    2    udp    819  rquotad
100005    1    udp    1027 mountd
100005    1    tcp    1106 mountd
100005    2    udp    1027 mountd
100005    2    tcp    1106 mountd
100005    3    udp    1027 mountd

```

```

100005  3  tcp   1106  mountd
100003  2  udp   2049  nfs
100003  3  udp   2049  nfs
100021  1  udp   1028  nlockmgr
100021  3  udp   1028  nlockmgr
100021  4  udp   1028  nlockmgr

```

The `-p` option probes the portmapper on the specified host or defaults to localhost if no specific host is listed. Other options are available from the `rpcinfo` man page.

From the output above, various NFS services can be seen running. If one of the NFS services does not start up correctly, `portmap` will be unable to map RPC requests from clients for that service to the correct port. In many cases, restarting NFS as root (`/sbin/service nfs restart`) will cause those service to correctly register with `portmap` and begin working.

17.2. NFS Server Configuration Files

Configuring a system to share files and directories using NFS is straightforward. Every file system being exported to remote users via NFS, as well as the access rights relating to those file systems, is located in the `/etc/exports` file. This file is read by the `exportfs` command to give `rpc.mountd` and `rpc.nfsd` the information necessary to allow the remote mounting of a file system by an authorized host.

The `exportfs` command allows you to selectively export or unexport directories without restarting the various NFS services. When `exportfs` is passed the proper options, the file systems to be exported are written to `/var/lib/nfs/xtab`. Since `rpc.mountd` refers to the `xtab` file when deciding access privileges to a file system, changes to the list of exported file systems take effect immediately.

Various options are available when using `exportfs`:

- `-r` — Causes all directories listed in `/etc/exports` to be exported by constructing a new export list in `/etc/lib/nfs/xtab`. This option effectively refreshes the export list with any changes that have been made to `/etc/exports`.
- `-a` — Causes all directories to be exported or unexported, depending on the other options passed to `exportfs`.
- `-o options` — Allows the user to specify directories to be exported that are not listed in `/etc/exports`. These additional file system shares must be written in the same way they are specified in `/etc/exports`. This option is used to test an exported file system before adding it permanently to the list of file systems to be exported.
- `-i` — Tells `exportfs` to ignore `/etc/exports`; only options given from the command line are used to define exported file systems.
- `-u` — Unexports directories from being mounted by remote users. The command `exportfs -ua` effectively suspends NFS file sharing while keeping the various NFS daemons up. To allow NFS sharing to continue, type `exportfs -r`.
- `-v` — Verbose operation, where the file systems being exported or unexported are displayed in greater detail when the `exportfs` command is executed.

If no options are passed to the `exportfs` command, it displays a list of currently exported file systems.

Changes to `/etc/exports` can also be read by reloading the NFS service with the `service nfs reload` command. This keeps the NFS daemons running while re-exporting the `/etc/exports` file.

17.2.1. `/etc/exports`

The `/etc/exports` file is the standard for controlling which file systems are exported to which hosts, as well as specifying particular options that control everything. Blank lines are ignored, comments can be made using `#`, and long lines can be wrapped with a backslash (`\`). Each exported file system should be on its own line. Lists of authorized hosts placed after an exported file system must be separated by space characters. Options for each of the hosts must be placed in parentheses directly after the host identifier, without any spaces separating the host and the first parenthesis.

In its simplest form, `/etc/exports` only needs to know the directory to be exported and the hosts permitted to use it:

```
/some/directory bob.domain.com
/another/exported/directory 192.168.0.3
```

After re-exporting `/etc/exports` with the `/sbin/service nfs reload` command, the `bob.domain.com` host will be able to mount `/some/directory` and `192.168.0.3` can mount `/another/exported/directory`. Because no options are specified in this example, several default NFS preferences take effect:

- `ro` — Read-only. Hosts mounting this file system will not be able to change it. To allow hosts to make changes to the file system, you must specify `rw` (read-write).
- `async` — Allows the server to write data to the disk when it sees fit. While this is not important if the host is accessing data as read-only, if a host is making changes to a read-write file system and the server crashes, data could be lost. By specifying the `sync` option, all file writes must be committed to the disk before the write request by the client is actually completed. This may lower performance.
- `wdelay` — Causes the NFS server to delay writing to the disk if it suspects another write request is imminent. This can improve performance by reducing the number of times the disk must be accessed by separate write commands, reducing write overhead. Use `no_wdelay` to turn this feature off, which only works if you are using the `sync` option.
- `root_squash` — Makes any client accesses to the exported file system, made as the root user on the client machine, take place as the nobody user ID. This effectively "squashes" the power of the remote root user to the lowest local user, preventing remote root users from acting as though they were the root user on the local system. Alternatively, the `no_root_squash` option turns off root squashing. To squash every remote user, including root, use the `all_squash` option. To specify the user and group IDs to use with remote users from a particular host, use the `anonuid` and `anongid` options, respectively. In this way, you can create a special user account for remote NFS users to share and specify `(anonuid=<uid-value>, anongid=<gid-value>)`, where `<uid-value>` is the user ID number and `<gid-value>` is the group ID number.

In order to override these defaults, you must specify an option that takes its place. For example, if you do not specify `rw`, then that export will only be shared read-only. Each default for every exported file system must be explicitly overridden. Additionally, other options are available where no default value is in place. These include the ability to disable sub-tree checking, allow access from insecure ports, and allow insecure file locks (necessary for certain early NFS client implementations). See the `exports` man page for details on these lesser used options.

When specifying hostnames, you can use the following methods:

- *single host* — Where one particular host is specified with a fully qualified domain name, hostname, or IP address.
- *wildcards* — Where a `*` or `?` character is used to take into account a grouping of fully qualified domain names or IP addresses or those that match a particular string of letters.

However, be careful when using wildcards with fully qualified domain names, as they tend to be more exact than you would expect. For example, the use of `*.domain.com` as wildcard will allow `sales.domain.com` to access the exported file system, but not `bob.sales.domain.com`. To match both possibilities, as well as `sam.corp.domain.com`, you would have to provide `*.*.domain.com`.

- *IP networks* — Allows the matching of hosts based on their IP addresses within a larger network. For example, `192.168.0.0/28` will allow the first 16 IP addresses, from `192.168.0.0` to `192.168.0.15`, to access the exported file system but not `192.168.0.16` and higher.
- *netgroups* — Permits an NIS netgroup name, written as `@<group-name>`, to be used. This effectively puts the NIS server in charge of access control for this exported file system, where users can be added and removed from an NIS group without affecting `/etc/exports`.

Warning

The way in which the `/etc/exports` file is formatted is very important, particularly concerning the use of space characters. Remember to always separate exported file systems from hosts and hosts from one another with a space character. However, there should be no other space characters in the file unless they are used in comment lines.

For example, the following two lines do not mean the same thing:

```
/home bob.domain.com(rw)
/home bob.domain.com (rw)
```

The first line allows only users from `bob.domain.com` read-write access to the `/home` directory. The second line allows users from `bob.domain.com` to mount the directory read-only (the default), but the rest of the world can mount it read-write. Be careful where space characters are used in `/etc/exports`.

17.3. NFS Client Configuration Files

Any NFS share made available by a server can be mounted using various methods. Of course, the share can be manually mounted, using the `mount` command, to acquire the exported file system at a particular mount point. However, this requires that the root user type the `mount` command every time the system restarts. In addition, the root user must remember to unmount the file system when shutting down the machine. Two methods of configuring NFS mounts include modifying the `/etc/fstab` or using the `autofs` service.

17.3.1. /etc/fstab

Placing a properly formatted line in the `/etc/fstab` file has the same effect as manually mounting the exported file system. The `/etc/fstab` file is read by the `/etc/rc.d/init.d/netfs` script at system startup. The proper file system mounts, including NFS, are put into place.

A sample `/etc/fstab` line to mount an NFS export looks like the following:

```
<server>:</path/of/dir> </local/mnt/point> nfs <options> 0 0
```

The `<server-host>` relates to the hostname, IP address, or fully qualified domain name of the server exporting the file system. The `</path/to/shared/directory>` tells the server what export to mount. The `</local/mount/point>` specifies where on the local file system to mount the exported directory. This mount point must exist before `/etc/fstab` is read or the mount will fail. The `nfs` option specifies the type of file system being mounted.

The `<options>` area specifies how the file system is to be mounted. For example, if the options area states `rw,suid` on a particular mount, the exported file system will be mounted read-write and the user and group ID set by the server will be used. Note, parentheses are not to be used here. For more mount options, see Section 17.3.3.

17.3.2. autofs

One drawback to using `/etc/fstab` is that, regardless of how much you use that mounted file system, your system must dedicate resources to keep that mount in place. This is not a problem with one or two mounts, but when your system is maintaining mounts to a dozen systems at one time, overall system performance can suffer. An alternative to `/etc/fstab` is to use the kernel-based `automount` utility, which will mount and unmount NFS file systems automatically, saving resources.

The `autofs` script, located in `/etc/rc.d/init.d`, is used to control `automount` through the `/etc/auto.master` primary configuration file. While `automount` can be specified on the command line, it is more convenient to specify the mount points, hostname, exported directory, and options in a set of files rather than typing them all by hand. By running `autofs` as a service that starts and stops in designated runlevels, the mount configurations in the various files can be automatically implemented. In order to use `autofs`, you must have the `autofs` RPM installed on your system.

The `autofs` configuration files are arranged in a parent-child relationship. A main configuration file (`/etc/auto.master`) refers mount points on your system that are linked to a particular *map type*, which take the form of other configuration files, programs, NIS maps, and other less common mount methods. The `auto.master` file contains lines referring to each of these mount points, organized like this:

```
<mount-point>    <map-type>
```

The `<mount-point>` indicates where the device or exported file system should mount on your local file system. The `<map-type>` relates to the way in which the mount point will be mounted. The most common method for auto mounting NFS exports is to use a file as the map type for the particular mount point. The map file, usually named `auto.<mount-point>`, where `<mount-point>` is the mount point designated in `auto.master`, contains lines that look like this:

```
<directory> <mount-options> <host>:<exported-file-system>
```

The `<directory>` refers to the directory within the mount point where the exported file system should be mounted. Much like a standard `mount` command, the host exporting the file system, as well as the file system being exported, are required in the `<host>:<exported-file system>` section. To specify particular options to be used when mounting the exported file system, place them in the `<mount-options>` section, separated by commas. For NFS mounts that use `autofs`, you should definitely place `-fstype=nfs` in the `<mount-options>` section, at a minimum.

While `autofs` configuration files can be used for a variety of mounts to many types of devices and file systems, they are particularly useful in creating NFS mounts. For example, some organizations store a user's `/home` directory on a central server via an NFS share. Then, they configure the `auto.master` file on each of the workstations to point to an `auto.home` file containing the specifics for how to mount the `/home` directory via NFS. This allows the user to access personal data and configuration files in their `/home` directory by logging in anywhere on the internal network. The `auto.master` file in this situation would look similar to this:

```
/home    /etc/auto.home
```

This sets up the `/home` mount point on the local system to be configured by the `/etc/auto.home` file, which may look similar to this:

```
* -fstype=nfs,soft,intr,rsize=8192,wsiz=8192,nosuid server.domain.com:/home/&
```

This line states that any directory a user tries to access under the local `/home` directory (due to the asterisk character) should result in an NFS mount on the `server.domain.com` system within its exported `/home` file system. The mount options specify that each `/home` directory NFS mounts should use a particular collection of settings. For more information on mount options, including the ones used in this example, see Section 17.3.3.

17.3.3. Common NFS Mount Options

Beyond mounting a file system via NFS on a remote host, a number of different options may be specified at the time of the mount that can make it easier to use. These options can be used with manual mount commands, `/etc/fstab` settings, and `autofs`, and other mounting methods.

The following options are the most popular for NFS mounts:

- `hard` or `soft` — specifies whether the program using a file via an NFS connection should stop and wait (`hard`) for the server to come back online if the host serving the exported file system is unavailable, or if it should report an error (`soft`).
If you specify `hard`, you will not be able to terminate the process waiting for the NFS communication to resume unless you also specify the `intr` option.
If you specify `soft`, you can set an additional `timeo=<value>` option, where `<value>` specifies the number of seconds to pass before the error is reported.
- `intr` — allows NFS requests to be interrupted if the server goes down or cannot be reached.
- `nolock` — is occasionally required when connecting to older NFS server. To require locking, use the `lock` option.
- `noexec` — does not permit the execution of binaries on the mounted file system. This is useful if your Red Hat Linux system is mounting a non-Linux file system via NFS that contains binaries that will not execute on your machine.
- `nosuid` — does not allow set-user-identifier or set-group-identifier bits to take effect.
- `rsize=8192` and `wsize=8192` — may speed up NFS communication for reads (`rsize`) and writes (`wsize`) by setting a larger data block size, in bytes, to be transferred at one time. Be careful when changing these values; some older Linux kernels and network cards may not work well with larger block sizes.
- `nfsvers=2` or `nfsvers=3` — specify which version of the NFS protocol to use.

Many more options are listed on the `mount` man page, including options for mounting non-NFS file systems.

17.4. Securing NFS

NFS works well for sharing entire file systems with a large number of known hosts in a largely transparent manner. Many users accessing files over an NFS mount may not be aware that the file system they are using is not local to their system. However, with ease of use comes a variety of potential security problems.

The following points should be considered when exporting NFS file systems on a server or mounting them on a client. Doing so will minimize NFS security risks and better protect your data.

17.4.1. Host Access

NFS controls who can mount an exported file system based on the host making the mount request, not the user that will actually use the file system. Hosts must be given explicit rights to mount the exported file system. Access control is not possible for users, other than file and directory permissions. In other words, when you export a file system via NFS to a remote host, you are not only trusting the host you are allowing to mount the file system. You are also allowing any user with access to that host to use your file system as well. The risks of doing this can be controlled, such as requiring read-only mounts and squashing users to a common user and group ID, but these solutions may prevent the mount from being used in the way originally intended.

Additionally, if an attacker gains control of the DNS server used by the system exporting the NFS file system, the system associated with a particular hostname or fully qualified domain name can be pointed to an unauthorized machine. At this point, the unauthorized machine *is* the system permitted to mount the NFS share, since no username or password information is exchanged to provide additional security for the NFS mount. The same risks hold true to compromised NIS servers, if NIS netgroups are used to allow certain hosts to mount an NFS share. By using IP addresses in `/etc/exports`, this kind of attack is more difficult.

Wildcards should be used sparingly when granting host access to an NFS share. The scope of the wildcard may encompass systems that you may not know exist and should not be allowed to mount the file system.

17.4.2. File Permissions

Once the NFS file system is mounted read-write by a remote host, protection for each shared file involves its permissions, and its user and group ID ownership. If two users that share the same user ID value mount the same NFS file system, they will be able to modify each others files. Additionally, anyone logged in as root on the client system can use the `su -` command to become a user who could access particular files via the NFS share.

The default behavior when exporting a file system via NFS is to use *root squashing*. This sets the user ID of anyone accessing the NFS share as the root user on their local machine to a value of the server's nobody account. You should never turn off root squashing unless multiple users with root access to your server does not bother you.

If you are only allowing users to read files via your NFS share, consider using the `all_squash` option, which makes every user accessing your exported file system to take the user ID of the nobody user.

17.5. Additional Resources

Administering an NFS server can be a challenge. Many options, including quite a few not mentioned in this chapter, are available for exporting NFS file systems or mounting them as a client. Consult these sources of information for more details.

17.5.1. Installed Documentation

- `/usr/share/doc/nfs-utils-<version-number>` — Covers the way NFS is implemented in Linux, including a look at various NFS configurations and their impact on file transfer performance.
- The following man pages are very helpful:
 - `mount` — Contains a comprehensive look at mount options for both NFS server and client configurations.

- `fstab` — Gives details for the format of the `/etc/fstab` file used to mount file systems at system boot.
- `nfs` — Provides detail on NFS-specific file system export and mount options.
- `exports` — Shows common options used in the `/etc/exports` file when exporting NFS file systems.

17.5.2. Related Books

- *Managing NFS and NIS* by Hal Stern, Mike Eisler, and Ricardo Labiaga; O'Reilly & Associates — Makes an excellent reference guide for the many different NFS export and mount options available.
- *NFS Illustrated* by Brent Callaghan; Addison-Wesley Publishing Company — Provides comparisons of NFS to other network file systems and shows, in detail, how NFS communication occurs.

Lightweight Directory Access Protocol (LDAP)

Lightweight Directory Access Protocol (LDAP) is a set of open protocols used to access centrally stored information over a network. It is based on the *X.500* standard for directory sharing, but is less complex and resource intensive. For this reason, LDAP is sometimes referred to as *X.500 Lite*.

Like *X.500*, LDAP organizes information in a hierarchal manner using directories. These directories can store a variety of information and can even be used in a manner similar to Network Information Service (NIS), enabling anyone to access their account from any machine on the LDAP enabled network.

In most cases, however, LDAP is used simply as a virtual phone directory, allowing users to easily access contact information for other users. But LDAP goes beyond a traditional phone directory, because it is capable of propagating its directories to other LDAP servers throughout the world, providing global access to information. Currently, however, LDAP is more commonly used within individual organizations, like universities, government departments, and private companies.

LDAP is a client-server system. The server can use a variety of databases to store a directory, each optimized for quick and copious read operations. When an LDAP client application connects to an LDAP server it can either query a directory or upload information to it. In the event of a query, the server either answers the query or, if it can not answer locally, it can refer the query upstream to a higher level LDAP server which does have the answer. If the client application is attempting to upload information to an LDAP directory, the server verifies that the user has permission to make the change and then adds or updates the information.

This chapter will refer to the configuration and use of OpenLDAP 2.0, an open source implementation of the LDAPv2 and LDAPv3 protocol.

18.1. Why Use LDAP?

The main benefit of LDAP is that information for an entire organization can be consolidated into a central repository. For example, rather than managing user lists for each group within an organization, you can use LDAP as a central directory accessible from anywhere on the network. And since LDAP supports Secure Sockets Layer (SSL) and Transport Layer Security (TLS), sensitive data can be protected from prying eyes.

LDAP also supports a number of back-end databases in which to store directories. This allows administrators the flexibility to deploy the database best suited for the type of information the server is to disseminate. Also, because LDAP has a well-defined Application Programming Interface (API), the number of LDAP-enabled applications are numerous and increasing in quantity and quality.

On the negative side, LDAP can be non-trivial to configure.

18.1.1. OpenLDAP 2.0 Feature Enhancements

OpenLDAP 2.0 includes a number of important features.

- *LDAPv3 Support* — OpenLDAP 2.0 supports Simple Authentication and Security Layer (SASL), Transport Layer Security (TLS), and Secure Sockets Layer (SSL), among other improvements. Many of the changes in the protocol since LDAPv2 are designed to make LDAP more secure.
- *IPv6 Support* — OpenLDAP supports the next generation Internet Protocol version 6.
- *LDAP Over IPC* — OpenLDAP can communicate within a system using interprocess communication (IPC). This enhances security by obviating the need to communicate over a network.

- *Updated C API* — Improves the way programmers can connect to and use the application.
- *LDIFv1 Support* — Full compliance with the LDAP Data Interchange Format (LDIF) version 1.
- *Enhanced Stand-Alone LDAP Server* — Includes an updated access control system, thread pooling, better tools and much more.

18.2. OpenLDAP Daemons and Utilities

The suite of OpenLDAP libraries and tools is spread out over the following packages:

- `openldap` — Contains the libraries necessary to run the `openldap` server and client applications.
- `openldap-clients` — Contains command-line tools for viewing and modifying directories on an LDAP server.
- `openldap-server` — Contains the servers and other utilities necessary to configure and run an LDAP server.

There are two servers contained in the `openldap-servers` package: the *Standalone LDAP Daemon* (`/usr/sbin/slapd`) and the *Standalone LDAP Update Replication Daemon* (`/usr/sbin/slurpd`).

The `slapd` daemon is the standalone LDAP server while the `slurpd` daemon is used to synchronize changes from one LDAP server to other LDAP servers on the network. The `slurpd` daemon is only necessary when dealing with multiple LDAP servers.

To perform administrative tasks, the `openldap-server` package installs the following utilities into the `/usr/sbin/` directory:

- `slapadd` — Adds entries from an LDIF file to an LDAP directory. For example, `/usr/sbin/slapadd -l ldif-input` will read in the LDIF file, `ldif-input`, containing the new entries.
- `slapcat` — Pulls entries out of an LDAP directory in the default format — Berkeley DB — and saves them in an LDIF file. For example, the command `/usr/sbin/slapcat -l ldif-output` will output an LDIF file called `ldif-output` containing the entries from the LDAP directory.
- `slapindex` — Re-indexes the `slapd` directory based on the current content.
- `slappasswd` — Generates an encrypted user password value for use with `ldapmodify` or the `rootpw` value in the `slapd` configuration file, `/etc/openldap/slapd.conf`. Execute `/usr/sbin/slappasswd` to create the password.

Warning

Be sure to stop `slapd` by issuing `/usr/sbin/service slapd stop` before using `slapadd`, `slapcat` or `slapindex`. Otherwise, the consistency of the LDAP directory is at risk.

See the man pages for each of these utilities for more information about how to use them.

The `openldap-clients` package installs tools used to add, modify, and delete entries in an LDAP directory into `/usr/bin/`. These tools include the following:

- `ldapmodify` — Modifies entries in an LDAP directory, accepting input via a file or standard input.
- `ldapadd` — Adds entries to your directory by accepting input via a file or standard input; `ldapadd` is actually a hard link to `ldapmodify -a`.

- `ldapsearch` — Searches for entries in the LDAP directory using a shell prompt.
- `ldapdelete` — Deletes entries from an LDAP directory by accepting input via user input at the terminal or via a file.

With the exception of `ldapsearch`, each of these utilities is more easily used by referencing a file containing the changes to be made rather than typing a command for each entry you wish to change in an LDAP directory. The format of such a file is outlined in each application's man page.

18.2.1. NSS, PAM, and LDAP

In addition to the OpenLDAP packages, Red Hat Linux includes a package called `nss_ldap` which enhances LDAP's ability to integrate into both Linux and other UNIX environments.

The `nss_ldap` package provides the following modules:

- `/lib/libnss_ldap-<glibc-version>.so`
- `/lib/security/pam_ldap.so`

The `libnss_ldap-<glibc-version>.so` module allows applications to look up user, group, hosts, and other information using an LDAP directory via `glibc`'s *Nameservice Switch* (NSS) interface. NSS allows applications to authenticate using LDAP in conjunction with *Network Information Service* (NIS) name service and flat authentication files.

The `pam_ldap` module allows PAM-aware applications to authenticate users using information stored in an LDAP directory. PAM-aware applications include console login, POP and IMAP mail servers, and Samba. By deploying an LDAP server on your network, all of these login situations can authenticate against one user ID and password combination, greatly simplifying administration.

18.2.2. PHP4, the Apache HTTP Server, and LDAP

Red Hat Linux includes a package containing LDAP module for the PHP server-side scripting language.

The `php-ldap` package adds LDAP support to the PHP4 HTML-embedded scripting language via the `/usr/lib/php4/ldap.so` module. This module allows PHP4 scripts to access information stored in an LDAP directory.

Important

Red Hat Linux 8.0 no longer ships with the `auth_ldap` package. This package provided LDAP support for versions 1.3 and earlier of the Apache HTTP Server. See the Apache Software Foundation website at <http://www.apache.org/> for details on the status of this module.

18.2.3. LDAP Client Applications

There are graphical LDAP clients available which support creating and modifying directories, but they do not ship with Red Hat Linux 8.0. One such application is **LDAP Browser/Editor** — A Java-based tool available at <http://www.iit.edu/~gawojar/ldap>.

Most other LDAP clients access directories as read-only, using them to reference, but not alter, organization-wide information. Some examples of such applications are Mozilla-based Web browsers, Sendmail **Balsa**, **Pine**, **Evolution**, **Gnome Meeting**.

18.3. LDAP Terminology

An *entry* is one unit in an LDAP directory. Each entry is identified by its unique Distinguished Name (DN).

Each entry has *attributes*, which are pieces of information directly associated with the entry. For example, an organization could be an LDAP entry. Attributes associated with the organization might be its fax number, its address, and so on. People can also be entries in the LDAP directory. Common attributes for people include the person's telephone numbers and email addresses.

Some attributes are required, while other attributes are optional. An *objectclass* definition sets which attributes are required and which are not for each entry. Objectclass definitions are found in various schema files, located in the `/etc/openldap/schema/` directory.

The *LDAP Data Interchange Format* (LDIF) is an ASCII text format for LDAP entries. Files that import or export data to and from LDAP servers must be in LDIF format. An LDIF entry looks similar to the following example:

```
[<id>]
dn: <distinguished name>
<attrtype>: <attrvalue>
<attrtype>: <attrvalue>
<attrtype>: <attrvalue>
```

An entry can contain as many `<attrtype>: <attrvalue>` pairs as needed. A blank line indicates the end of an entry.

Caution

All `<attrtype>` and `<attrvalue>` pairs *must* be defined in a corresponding schema file to use this information.

Any value enclosed within a `<` and a `>` is a variable and can be set whenever a new LDAP entry is created, except for `<id>`. The `<id>` is a number determined by the application you use to edit the entry.

Note

You should never need to edit an LDIF entry by hand. Instead use an LDAP client application, such as the ones listed in Section 18.2.

18.4. OpenLDAP Configuration Files

OpenLDAP configuration files are installed into the `/etc/openldap/` directory. The following is a brief list highlighting the most important directories and files:

- `/etc/openldap/schema/` directory — This subdirectory contains the schema used by the `slapd` daemon. See Section 18.4.2 for more information about this directory.
- `/etc/openldap/ldap.conf` — This is the configuration file for all *client* applications which use the OpenLDAP libraries. These include, but are not limited to, Sendmail, **Pine**, **Balsa**, **Evolution**, and **Gnome Meeting**.

- `/etc/openldap/slapd.conf` — This is the configuration file for the `slapd` daemon. See Section 18.4.1 for more information about this file.

**Note**

If the `nss_ldap` package is installed, it will create a file named `/etc/ldap.conf`. This file is used by the PAM and NSS modules supplied by the `nss_ldap` package. See Section 18.7 for more information about this configuration file.

18.4.1. slapd.conf

In order to use the `slapd` LDAP server, you will need to modify its configuration file, `/etc/openldap/slapd.conf`. You must to edit this file to make it specific to your domain and server.

The `suffix` line names the domain for which the LDAP server will provide information. The `suffix` line should be changed from:

```
suffix          "dc=your-domain,dc=com"
```

so that it reflects your domain name. For example:

```
suffix          "dc=example,dc=com"
```

The `rootdn` entry is the *Distinguished Name (DN)* for a user who is unrestricted by access controls or administrative limit parameters set for operations on the LDAP directory. The `rootdn` user can be thought of as the root user for the LDAP directory. In the configuration file, change the `rootdn` line from its default value to something like the example below:

```
rootdn          "cn=root,dc=example,dc=com"
```

Change the `rootpw` line to something like the example below:

```
rootpw          {SSHA}vv2y+i6V6esazrIv70xSSnNAJE18bb2u
```

In the `rootpw` example, you are using an encrypted root password, which is a much better idea than leaving a plain text root password in the `slapd.conf` file. To make this encrypted string, type the following command:

```
slappasswd
```

You will be prompted to type and then re-type a password. The program prints the resulting encrypted password to the terminal.

**Warning**

LDAP passwords, including the `rootpw` directive specified in `/etc/openldap/slapd.conf`, are sent over the network in plain text unless you enable TLS encryption.

For added security, the `rootpw` directive should only be used if the initial configuration and population of the LDAP directory occurs over a network. After the task is completed, it is best to comment out the `rootpw` directive by preceding it with a pound sign (`#`).

**Tip**

If you are using the `slapadd` command-line tool locally to populate the LDAP directory, using the `rootpw` directive is not necessary.

18.4.2. The `/etc/openldap/schema/` Directory

The `/etc/openldap/schema/` directory holds LDAP definitions, previously located in the `slapd.at.conf` and `slapd.oc.conf` files. All *attribute syntax definitions* and *objectclass definitions* are now located in the different schema files. The various schema files are referenced in `/etc/openldap/slapd.conf` using `include` lines, as shown in this example:

```
include /etc/openldap/schema/core.schema
include /etc/openldap/schema/cosine.schema
include /etc/openldap/schema/inetorgperson.schema
include /etc/openldap/schema/nis.schema
include /etc/openldap/schema/rfc822-MailMember.schema
include /etc/openldap/schema/autofs.schema
include /etc/openldap/schema/kerberosobject.schema
```

**Caution**

You should not modify any of the schema items defined in the schema files installed by OpenLDAP.

You can extend the schema used by OpenLDAP to support additional attribute types and object classes using the default schema files as a guide. To do this, create a `local.schema` file in the `/etc/openldap/schema` directory. Reference this new schema within `slapd.conf` by adding the following line below your default `include` schema lines:

```
include /etc/openldap/schema/local.schema
```

Next, go about defining your new attribute types and object classes within the `local.schema` file. Many organizations use existing attribute types and object classes from the schema files installed by default and modify them for use in the `local.schema` file. This can help you to learn the schema syntax while meeting the immediate needs of your organization.

Extending schema to match certain specialized requirements is quite involved and beyond the scope of this chapter. Visit <http://www.openldap.org/doc/admin/schema.html> for information on writing new schema files.

18.5. OpenLDAP Setup Overview

This section provides a quick overview for installing and configuring an OpenLDAP directory. For more details, refer to the following URLs:

- <http://www.openldap.org/doc/admin/quickstart.html> — The *Quick-Start Guide* on the OpenLDAP website.
- <http://www.redhat.com/mirrors/LDP/HOWTO/LDAP-HOWTO.html> — The *LDAP Linux HOWTO* from the Linux Documentation Project, mirrored on Red Hat's website

The basic steps for creating an LDAP server are as follows:

1. Install the `openldap`, `openldap-servers`, and `openldap-clients` RPMs.
2. Edit the `/etc/openldap/slapd.conf` file to reference your LDAP domain and server. Refer to Section 18.4.1 for more information on how to edit this file.
3. Start `slapd` with the command:

```
/sbin/service/ldap start
```

After you have configured LDAP correctly, you can use `chkconfig`, `ntsysv`, or **Services Configuration Tool** to configure LDAP to start at boot time. For more information about configuring services, see to the chapter titled *Controlling Access to Services* in the *Official Red Hat Linux Customization Guide*.

4. Add entries to your LDAP directory with `ldapadd`.
5. Use `ldapsearch` to see if `slapd` is accessing the information correctly.
6. At this point, your LDAP directory should be functioning properly and you can configure any LDAP-enabled applications to use the LDAP directory.

18.6. Upgrading To OpenLDAP Version 2.0

In OpenLDAP Version 2.0, the on-disk storage format used by the `slapd` LDAP server has changed. If you are upgrading LDAP from Red Hat Linux 7.0 or earlier, you will need to extract the existing LDAP directories to an LDIF file using the following command:

```
ldbmcats -n > <ldif_file>
```

In the above command, change `<ldif_file>` to the name of the output file. Next type the following command to import this file into OpenLDAP 2.0:

```
slapadd -l <ldif_file>
```

18.7. Configuring Your System to Authenticate Using OpenLDAP

This section provides a brief overview of how to configure a Red Hat Linux system to authenticate using OpenLDAP. Unless you are an OpenLDAP expert, you will probably need more documentation than is provided here. Please refer to the references provided in Section 18.8 for more information.

18.7.1. Install the Necessary LDAP Packages

First, you should make sure that the appropriate packages are installed on both the LDAP server and the LDAP client machines. The LDAP server needs the `openldap-server` package.

The LDAP client machines need the following packages installed: `openldap`, `openldap-clients`, and `nss_ldap`.

18.7.2. Edit the Configuration Files

18.7.2.1. On the Server, Edit `slapd.conf`

Edit the `/etc/openldap/slapd.conf` file on the LDAP server to make sure it matches the specifics of your organization. Please refer to Section 18.4.1 for instructions on editing `slapd.conf`.

18.7.2.2. On the Clients, Edit `/etc/ldap.conf` and `/etc/openldap/ldap.conf`

On all client machines, both `/etc/ldap.conf` and `/etc/openldap/ldap.conf` need to contain the proper server and search base information for your organization.

The simplest way to do this is to run the **authconfig** application and select **Use LDAP** on the the **User Information Configuration** screen.

You can also edit these files by hand.

18.7.2.3. On the Clients, Edit `/etc/nsswitch.conf`

On all client machines, the `/etc/nsswitch.conf` must be edited to use LDAP.

The simplest way to do this is to run the **authconfig** application and select **Use LDAP** on the the **User Information Configuration** screen.

If editing `/etc/nsswitch.conf` by hand, add `ldap` to the appropriate fields.

For example:

```
passwd: files ldap
shadow: files ldap
group: files ldap
```

18.7.2.4. PAM and LDAP

To have standard PAM-enabled applications use LDAP for authentication, run **authconfig** and select **Use LDAP Authentication** on the the **Authentication Configuration** screen. For more on configuring PAM consult, Chapter 7 and the PAM man pages.

18.7.3. Migrating Old Authentication Information to LDAP Format

The `/usr/share/openldap/migration/` directory contains a set of shell and Perl scripts for migrating authentication information into LDAP format.

Note

You must have Perl installed on your system to use these scripts.

First, you will need to modify the `migrate_common.ph` file so that it reflects your domain. The default DNS domain should be changed from its default value to something like:

```
$DEFAULT_MAIL_DOMAIN = "your_company";
```

The default base should also be changed, to something like:

```
$DEFAULT_BASE = "dc=your_company,dc=com";
```

The job of migrating a user database into a format LDAP can read falls to a group of migration scripts installed with the `nss_ldap` package. Using Table 18-1, decide which script to run in order to migrate your user database.

Existing name service	Is LDAP running?	Script to Use
/etc flat files	yes	migrate_all_online.sh
/etc flat files	no	migrate_all_offline.sh
NetInfo	yes	migrate_all_netinfo_online.sh
NetInfo	no	migrate_all_netinfo_offline.sh
NIS (YP)	yes	migrate_all_nis_online.sh
NIS (YP)	no	migrate_all_nis_offline.sh

Table 18-1. LDAP Migration Scripts

Run the appropriate script based on your existing name service.

The `README` and the `migration-tools.txt` files in the `/usr/share/openldap/migration` directory provide more details on how to migrate the information.

18.8. Additional Resources

More information concerning LDAP is available. Please review these sources, especially the OpenLDAP website and the LDAP HOWTO, before configuring LDAP on your system.

18.8.1. Installed Documentation

- LDAP man pages — The `ldap` man page is a good place to get started for an introduction to LDAP. Man pages also exist for the various LDAP daemons and utilities.
- `/usr/share/docs/openldap-<versionnumber>` — Contains a general `README` document and miscellaneous information.

18.8.2. Useful Websites

- <http://www.openldap.org> — Home of the OpenLDAP Project. This website contains a wealth of information about configuring OpenLDAP.
- <http://www.redhat.com/mirrors/LDP/HOWTO/LDAP-HOWTO.html> — An older, but still relevant LDAP HOWTO.
- <http://www.padl.com> — Developers of `nss_ldap` and `pam_ldap`, among other useful LDAP tools.
- <http://www.kingsmountain.com/ldapRoadmap.shtml> — Jeff Hodges' LDAP Road Map contains links to several useful FAQs and emerging news concerning the LDAP protocol.
- <http://www.webtechniques.com/archives/2000/05/wilcox> — A useful look at managing groups in LDAP.
- <http://www.ldapman.org/articles> — Articles that offer a good introduction to LDAP, including methods to design an directory tree and customizing directory structures.

18.8.3. Related Books

- *Implementing LDAP* by Mark Wilcox; Wrox Press, Inc.
- *Understanding and Deploying LDAP Directory Services* by Tim Howes et al.; Macmillan Technical Publishing

Appendixes

General Parameters and Modules

This appendix is provided to illustrate *some* of the possible parameters available for some common hardware device drivers¹. In most cases, these additional parameters are unnecessary, since the kernel may already be able to use the device without them. You should only use the settings provided in this appendix if you are having trouble getting Red Hat Linux to use a particular device or you need to override the system's default parameters for the device.

During the installation of Red Hat Linux, some limits are placed on file systems and some device drivers supported by the kernel. After installation, however, support exists for all file systems available under Linux. At the time of installation, the modularized kernel has support for (E)IDE devices (including ATAPI CD-ROM drives), SCSI adapters, and network cards.

Note

Because Red Hat Linux supports installation on many different types of hardware, some drivers (including those for SCSI adapters, network cards, and many CD-ROMs) are not built into the Linux kernel used by the installation program. Rather, they are available as modules and are loaded as you need them during the installation process. If necessary, you will have the chance to specify options for these modules when they are loaded from the driver disk.

To specify module parameters when a driver is loaded, type **linux expert** at the `boot:` prompt and insert the driver disk when prompted to do so by the installation program. After reading the driver disk, the installation program will ask you to select the type of device you are configuring. On that screen, you can elect to specify a module parameter. Then, the installation program will display a screen where you can type the correct parameters based on the particular type of device you are configuring.

After the installation is complete, you may want to rebuild a kernel that includes support for your specific hardware configuration. Note that in most cases, a custom-built kernel is not necessary. See the *Official Red Hat Linux Customization Guide* for more information about rebuilding your kernel.

A.1. Specifying Module Parameters

If you are providing parameters upon loading a module, you can usually specify them using one of two different methods:

- Specify a full set of parameters in one statement. For example, the parameter `cdu31=0x340,0` could be used with a Sony CDU 31 or 33 at port 340 with no IRQ.
- Specify the parameters individually. This method is used when one or more parameters in the first set are not needed. For example, `cdu31_port=0x340 cdu31a_irq=0` can be used as the parameter for the same CD-ROM used as an example for the first method. An *OR* is used in the CD-ROM, SCSI, and Ethernet tables in this appendix to show where the first parameter method stops and the second method begins.

1. A *driver* is software enabling your system to use a particular hardware device. Without the driver, the kernel may not know how to correctly access the device.

**Note**

Only use one method, and not both, when loading a module with particular parameters.

**Caution**

When a parameter has commas, make sure you do *not* put a space after a comma.

A.2. CD-ROM Module Parameters

**Note**

Not all of the CD-ROM drives that are listed are supported. Please check the Hardware Compatibility List on Red Hat's website at <http://hardware.redhat.com> to make sure your CD-ROM drive is supported.

Even though parameters are specified after loading the driver disk and specifying the device, one of the more commonly used parameters (`hdX=cdrom`) *can* be entered at the boot prompt (`boot:`) during installation. This exception to the rule is allowed since it deals with support for IDE/ATAPI CD-ROMs, which is already part of the kernel.

In the following tables, most modules listed without any parameters can either be auto-probed to find the hardware or they require you to manually change settings in the module source code and recompile.

Hardware	Module	Parameters
ATAPI/IDE CD-ROM Drives		<code>hdX=cdrom</code>
Aztech CD268-01A, Orchid CD-3110, Okano/Wearnes CDD110, Conrad TXC, CyCDROM CR520, CyCDROM CR540 (non-IDE)	<code>aztcd.o</code>	<code>aztcd=io_port</code>
Sony CDU-31A CD-ROM	<code>cdu31a.o</code>	<code>cdu31a=io_port,IRQ OR cdu31a_port=base_addr cdu31a_irq=irq</code>
Philips/LMS CDROM drive 206 with cm260 host adapter card	<code>cm206.o</code>	<code>cm206=io_port,IRQ</code>
Goldstar R420 CD-ROM	<code>gsd.o</code>	<code>gsd=io_port</code>

Hardware	Module	Parameters
ISP16, MAD16, or Mozart sound card CD-ROM interface (OPTi 82C928 and OPTi 82C929) with Sanyo/Panasonic, Sony, or Mitsumi drives	isp16.o	isp16= <i>io_port</i> , <i>IRQ</i> , <i>dma</i> , <i>drive_type</i> <i>OR</i> isp16_cdrom_base= <i>io_port</i> isp16_cdrom_irq= <i>IRQ</i> isp16_cdrom_dma= <i>dma</i> isp16_cdrom_type= <i>drive_type</i>
Mitsumi CD-ROM, Standard	mcd.o	mcd= <i>io_port</i> , <i>IRQ</i>
Mitsumi CD-ROM, Experimental	mcdx.o	mcdx= <i>io_port_1</i> , <i>IRQ_1</i> , <i>io_port_n</i> , <i>IRQ_n</i>
Optics storage 8000 AT "Dolphin" drive, Lasermate CR328A	optcd.o	
Parallel-Port IDE CD-ROM	pcd.o	
SB Pro 16 Compatible	sbpcd.o	sbpcd= <i>io_port</i>
Sanyo CDR-H94A	sjcd.o	sjcd= <i>io_port</i> <i>OR</i> sjcd_base= <i>io_port</i>
Sony CDU-535 & 531 (some Procomm drives)	sonycd535.o	sonycd535= <i>io_port</i>

Table A-1. Hardware Parameters

Here are some examples of these modules in use:

Configuration	Example
ATAPI CD-ROM, jumpered as master on the second IDE channel	hdc=cdrrom
non-IDE Mitsumi CD-ROM on port 340, IRQ 11	mcd=0x340,11
Three non-IDE Mitsumi CD-ROM drives using the experimental driver, io ports 300, 304, and 320 with IRQs 5, 10 and 11	mcdx=0x300,5,0x304,10,0x320,11
Sony CDU 31 or 33 at port 340, no IRQ	cdu31=0x340,0 <i>OR</i> cdu31_port=0x340 cdu31a_irq=0
Aztech CD-ROM at port 220	aztcd=0x220
Panasonic-type CD-ROM on a SoundBlaster interface at port 230	sbpcd=0x230,1
Phillips/LMS cm206 and cm260 at IO 340 and IRQ 11	cm206=0x340,11
Goldstar R420 at IO 300	gscd=0x300
Mitsumi drive on a MAD16 soundcard at IO Addr 330 and IRQ 1, probing DMA	isp16=0x330,11,0,Mitsumi
Sony CDU 531 at IO address 320	sonycd535=0x320

Table A-2. Hardware Parameters Configuration Examples

**Note**

Most newer Sound Blaster cards come with IDE interfaces. For these cards, you do not need to use `sbpcd` parameters; only use `hdX` parameters.

A.3. SCSI parameters

Hardware	Module	Parameters
Adaptec 28xx, R9xx, 39xx	<code>aic7xxx.o</code>	
3ware Storage Controller	<code>3w-xxxx.o</code>

Table A-5. Ethernet Module Parameters

Here are some examples of these modules in use:

Configuration	Example
NE2000 ISA card at IO address 300 and IRQ 11	ne=0x300,11 ether=0x300,11,eth0
Wavelan card at IO 390, autoprobe for IRQ, and use the NWID to 0x4321	wavelan=0,0x390,0x4321 ether=0,0x390,0x4321,eth0

Table A-6. Ethernet Parameter Configuration Examples

A.4.1. Using Multiple Ethernet Cards

You can use multiple Ethernet cards in one machine. If each card uses a different driver (for example, a 3c509 and a DE425), you simply need to add `alias` (and possibly `options`) lines for each card to `/etc/modules.conf`. See the *Official Red Hat Linux Customization Guide* for more information.

If any two Ethernet cards use the same driver (such as two 3c509 cards or a 3c595 and a 3c905), you will need to either give the two card addresses on the driver's options line (for ISA cards) or simply add one `alias` line for each card (for PCI cards).

For additional information about using more than one Ethernet card, see the *Linux Ethernet-HOWTO* at <http://www.redhat.com/mirrors/LDP/HOWTO/Ethernet-HOWTO.html>.

The Official Red Hat Linux manuals are written in DocBook SGML v4.1 format. The HTML and PDF formats are produced using custom DSSSL stylesheets and custom jade wrapper scripts.

Marianne Pecci <goddess@ipass.net> created the admonition graphics (note, tip, important, caution, and warning). They may be redistributed with written permission from Marianne Pecci and Red Hat, Inc..

The Red Hat Linux Product Documentation Team consists of the following people:

Sandra A. Moore — Primary Writer/Maintainer of the *Official Red Hat Linux x86 Installation Guide*; Contributing Writer to the *Official Red Hat Linux Getting Started Guide*

Tammy Fox — Primary Writer/Maintainer of the *Official Red Hat Linux Customization Guide*; Contributing Writer to the *Official Red Hat Linux Getting Started Guide*; Writer/Maintainer of custom DocBook stylesheets and scripts

Edward C. Bailey — Contributing Writer to the *Official Red Hat Linux x86 Installation Guide*

Johnray Fuller — Primary Writer/Maintainer of the *Official Red Hat Linux Reference Guide*; Co-writer/Co-maintainer of the *Official Red Hat Linux Security Guide*

John Ha — Primary Writer/Maintainer to the *Official Red Hat Linux Getting Started Guide*; Co-writer/Co-maintainer of the *Official Red Hat Linux Security Guide*
